PROCEEDINGS

OF THE

AMERICAN SOCIETY OF CIVIL ENGINEERS

VOL. 62 OCTOBER, 1936 NO. 8, PART 2

TRANSACTIONS

NUMBER 101

1936

PUBLISHED BY THE SOCIETY
1936

**Entered as Second-Class Matter, December 28, 1931,
at the Post Office at Albany, N. Y., under the
Act of March 3, 1879. Acceptance for
mailing at special rate of postage
provided for in Section 1103,
Act of October 3, 1917,
authorized on
July 5, 1918**

***Published at 99–129 North Broadway, Albany, N. Y.,
by the American Society of Civil Engineers***

PAPERS

No. PAGE

1923 WEIGHTS OF METAL IN STEEL TRUSSES.
By J. A. L. Waddell 1
Discussion:
By ARTHUR M. SHAW 12
JOSEPH G. SHRYOCK 13
ALBERT F. REICHMANN 13
ROBERT W. ABBETT 14
GEORGE C. DIEHL 15
F. G. JONAH 16
CLARENCE D. FOIGHT 16
A. H. FULLER 18
WILLIAM E. WILBUR 19
W. N. DOWNEY 21
J. R. GRANT 23
THERON M. RIPLEY 24
T. KENNARD THOMSON 26
H. H. ALLEN 27
JOHN VENABLE HANNA 29
J. A. L. WADDELL 30

1924 AN ASYMMETRIC PROBABILITY FUNCTION.
By J. J. Slade, Jr. 35
Discussion:
By GORDON R. WILLIAMS 62
H. ALDEN FOSTER 63
R. D. GOODRICH 64
F. T. MAVIS 67
L. STANDISH HALL 69
ARNE FISHER 72
ARTHUR W. KEMPERT 88
J. J. SLADE, JR. 91

1925 ANALYSIS OF CONTINUOUS STRUCTURES BY TRAVERSING THE ELASTIC CURVES.
By Ralph W. Stewart 105
Discussion:
By GARRETT B. DRUMMOND 115
AUSTIN H. REEVES 116
E. G. PAULET 116
ADOLPHUS MITCHELL 118
DAVID M. WILSON 119
W. H. KIRKBRIDE 120
R. B. KETCHUM 121
A. FLORIS 121
IVAN M. NELIDOV 121
FANG-YIN TSAI 126
RALPH W. STEWART 130

No. PAGE

1926 RELATION BETWEEN RAINFALL AND RUN-OFF FROM SMALL URBAN AREAS.
By **W. W. Horner and F. L. Flynt** 140
Discussion:
By FRANKLIN F. SNYDER 184
MERRILL M. BERNARD 186
LEROY K. SHERMAN 194
W. W. HORNER AND F. L. FLYNT 196

1927 THE SILT PROBLEM.
By **J. C. Stevens** 207
Discussion:
By HARRY G. NICKLE 251
E. W. LANE 255
FRANK E. BONNER 261
MORROUGH P. O'BRIEN 263
HARRY F. BLANEY 265
W. W. WAGGONER 268
PHILIP R. R. BISSCHOP 271
HERMAN STABLER 277
N. C. GROVER 284
J. C. STEVENS 286

1928 EFFECT OF SECONDARY STRESSES UPON ULTIMATE STRENGTH.
By **John I. Parcel and Eldred B. Murer** 289
Discussion:
By C. H. SANDBERG 327
J. D. GEDO 327
L. E. GRINTER 328
L. T. EVANS 330
F. E. FAHY 331
LAMOTTE GROVER 336
A. A. EREMIN 337
JOHN I. PARCEL AND ELDRED B. MURER 338

1929 THE SPRINGWELLS FILTRATION PLANT, DETROIT, MICHIGAN.
By **Eugene A. Hardin** 344
Discussion:
By F. H. SFEPHENSON 383
ROBERT SPURR WESTON 383
EUGENE A. HARDIN 385

1930 ANALYSIS OF MULTIPLE ARCHES.
By **Alexander Hrennikoff** 388
Discussion:
By L. E. GRINTER 406
N. M. NEWMARK 407
T. Y. LIN 410
A. H. FINLAY 410
A. W. FISCHER 416
A. A. EREMIN 418
ALEXANDER HRENNIKOFF 419

1931 RATIONAL DESIGN OF STEEL COLUMNS.
By **D. H. Young** 422
Discussion:
By WILLIAM R. OSGOOD 452
ALFRED S. NILES 453
J. F. BAKER 455

No. Page

K. L. De Blois 460
Marvin A. Gray 464
R. G. Sturm and Marshall Holt 467
F. E. Turneaure 471
N. J. Durant 473
E. C. Hartmann 475
Edward Godfrey 482
L. T. Wyly 483
D. H. Young 493

1932 **ANALYSIS OF THICK ARCH DAMS, INCLUDING ABUTMENT YIELD.**
By **Philip Cravitz** 501

Discussion:
By I. M. Nelidov 514
A. Floris 521
Philip Cravitz 522

1933 **ELASTIC PROPERTIES OF RIVETED CONNECTIONS.**
By **J. Charles Rathbun** 524

Discussion:
By Ralph E. Goodwin 564
Harold C. Rowan 566
Walter Scholtz 568
J. F. Baker 569
L. E. Grinter 571
C. R. Young and K. B. Jackson 574
E. Mirabelli 580
R. L. Moore 582
John Sanford Peck 588
J. Charles Rathbun 591

1934 **HYDRAULIC LABORATORY RESULTS AND THEIR VERIFICATION IN NATURE.**
By **Herbert D. Vogel** 597

Discussion:
By W. F. Heavey 614
Chilton A. Wright 615
Paul S. Reinecke 616
Morrough P. O'Brien 618
John A. Jameson, Jr 620
J. C. Stevens 622
Paul W. Thompson 624
Samuel Shulits 625
Herbert D. Vogel 627

1935 **THE HYDRAULIC JUMP IN TERMS OF DYNAMIC SIMILARITY.**
By **Boris A. Bakhmeteff and Arthur E. Matzke** 630

Discussion:
By Hunter Rouse 648
Sherman M. Woodward 651
Robert E. Kennedy 653
L. Standish Hall 655
Morrough P. O'Brien 656
F. V. A. E. Engel 657
Baldwin M. Woods 659
J. C. Stevens 660
Nolan Page 664
Andrei I. Ivanchenko 668
F. T. Mavis and Andreas Luksch 669
I. M. Nelidov 672
Boris A. Bakhmeteff and Arthur E. Matzke 673

No. PAGE

1936. FRICTIONAL RESISTANCE IN ARTIFICIALLY ROUGHENED PIPES.
By Victor L. Streeter........ 681
Discussion:
By WARREN E. WILSON........ 705
RICHARD G. FOLSOM........ 707
RALPH W. POWELL........ 709
VICTOR L. STREETER........ 712

1937 STABILIZING CONSTRUCTED MASONRY DAMS BY MEANS OF CEMENT INJECTIONS.
By D. W. Cole........ 714
Discussion:
By OREN REED........ 752
F. F. FERGUSSON........ 754
JOSEPH WRIGHT........ 755
CHARLES W. COMSTOCK........ 756
V. L. MINEAR........ 760
JAMES B. HAYS........ 762
D. W. COLE........ 764

1938 LINE LOAD ACTION ON THIN CYLINDRICAL SHELLS.
By Herman Schorer........ 767
Discussion:
By I. K. SILVERMAN........ 803
W. FLÜGGE........ 805
ANTON TEDESKO........ 806
U. FINSTERWALDER........ 808
F. W. SEIDENSTICKER........ 809
HERMAN SCHORER........ 810

1939 UNDERGROUND CORROSION.
By K. H. Logan........ 811
Discussion:
By THOMAS F. WOLFE........ 826
JOHN R. BAYLIS........ 828
E. P. FETHERSTONHAUGH........ 828
JOHN F. SKINNER........ 830
F. N. SPELLER........ 832
K. H. LOGAN........ 832

1940 THE ADJUSTMENT OF A LEVEL NET.
By George H. Dell........ 834
Discussion:
By EARL F. CHURCH........ 853
W. H. RAYNER........ 854
GEORGE H. DELL........ 856

1941 STRUCTURAL BEAMS IN TORSION.
By Inge Lyse and Bruce G. Johnston........ 857
Discussion:
By H. M. WESTERGAARD AND R. D. MINDLIN........ 897
JOSEPH B. REYNOLDS........ 899
HAROLD E. WESSMAN........ 904
F. B. SEELY AND W. J. PUTNAM........ 907
P. WILHELM WERNER........ 912
F. L. EHASZ........ 918
W. P. ROOP AND JOHN B. LETHERBURY........ 921
ALFRED T. WAIDELICH........ 923
INGE LYSE AND BRUCE G. JOHNSTON........ 924

No. PAGE

1942 PHOTO-ELASTIC DETERMINATION OF SHRINKAGE STRESSES.
By Howard G. Smits 927
Discussion:
By Thomas H. Evans 935
I. K. Silverman 935
J. H. A. Brahtz 936
Arshag G. Solakian 937
L. N. G. Filon 941
Howard G. Smits 943

1943 THE SHEAR-AREA METHOD.
By Horace B. Compton and Clayton O. Dohrenwend 945
Discussion:
By George E. Large 964
Samuel T. Carpenter 966
Roland H. Trathen 968
A. W. Fischer 970
J. Charles Rathbun 973
Harold R. Kepner 976
Fred L. Plummer 983
Albin H. Beyer 984
John M. Beatty 988
R. B. Peck 992
Ralph W. Stewart 993
C. W. Johnson and H. W. Birkeland 995
Garrett B. Drummond 1001
Harold E. Wessman 1002
Fang-Yin Tsai 1003
David A. Molitor 1007
F. Muls-Guinotte 1008
Horace B. Compton and Clayton O. Dohrenwend 1010

1944 FLOOD-STAGE RECORDS OF THE RIVER NILE.
By C. S. Jarvis 1012
Discussion:
By Halbert P. Gillette 1031
R. W. Davenport 1033
H. E. Hurst 1036
Thomas H. Means 1040
J. W. Beardsley 1045
J. C. Stevens 1048
Jesse W. Shuman 1049
Kamel Osman Ghaleb 1063
C. S. Jarvis 1067

1945 DISTRIBUTION OF STRESSES UNDER A FOUNDATION.
By A. E. Cummings 1072
Discussion:
By Clement C. Williams 1084
D. P. Krynine 1085
L. C. Wilcoxen 1092
Marshall G. Findley 1095
M. A. Biot 1097
Jacob Feld 1097
George Paaswell 1099
G. S. Salter 1100
W. S. Housel 1101
N. M. Newmark 1115
A. A. Eremin 1117
A. Casagrande 1119
A. E. Cummings 1126

No. PAGE

1946 SOME LOW-TEMPERATURE CHARACTERISTICS OF BITUMINOUS PAVING COMPOSITIONS.
By Hugh W. Skidmore 1135

Discussion:
By PHILIP W. HENRY 1151
J. T. L. MCNEW 1152
ROY M. GREEN 1155
W. W. CROSBY 1155
JOSEPH ZAPATA 1156
M. HIRSCHTHAL 1158
HUGH W. SKIDMORE 1159

1947 FAILURE THEORIES OF MATERIALS SUBJECTED TO COMBINED STRESSES.
By Joseph Marin 1162

Discussion:
By J. J. SLADE, JR. 1179
T. MCLEAN JASPER 1187
I. K. SILVERMAN 1188
W. P. ROOP 1189
H. F. MOORE 1190
A. A. EREMIN 1191
A. FLORIS 1192
JOSEPH MARIN 1193

1948 ADAPTATION OF VENTURI FLUMES TO FLOW MEASUREMENTS IN CONDUITS.
By Harold K. Palmer and Fred D. Bowlus 1195

Discussion:
By N. F. HOPKINS 1217
HUNTER ROUSE 1218
F. V. A. E. ENGEL 1226
J. C. STEVENS 1229
FILIPPO ARREDI 1231
HAROLD K. PALMER AND FRED D. BOWLUS 1235

1949 THE STRESS FUNCTION AND PHOTO-ELASTICITY APPLIED TO DAMS.
By John H. A. Brahtz 1240

Discussion:
By I. K. SILVERMAN 1278
FRED L. PLUMMER 1281
ARSHAG G. SOLAKIAN 1283
LARS R. JORGENSEN 1284
ELMER O. BERGMAN 1287
D. P. KRYNINE 1288
JOHN H. A. BRAHTZ 1295

1950 FLOOD AND EROSION CONTROL PROBLEMS AND THEIR SOLUTION.
By E. Courtlandt Eaton 1302

Discussion:
By ARTHUR G. PICKETT 1331
R. W. DAVENPORT 1333
C. S. JARVIS 1335
HARRY F. BLANEY 1337
W. P. ROWE 1340
J. B. LIPPINCOTT 1344
E. I. KOTOK AND C. J. KRAEBEL 1350
DONALD M. BAKER 1356
E. COURTLANDT EATON 1359

No. PAGE

1951 THE RELATION OF ANALYSIS TO STRUCTURAL DESIGN.

By Hardy Cross 1363

Discussion:

By L. J. MENSCH 1375

RUSSELL C. BRINKER 1380

MARSHALL G. FINDLEY 1380

I. K. SILVERMAN 1388

BRUCE G. JOHNSTON 1389

HAROLD E. WESSMAN 1391

N. M. NEWMARK 1395

L. E. GRINTER 1400

F. P. SHEARWOOD 1405

HARDY CROSS 1406

1952 TUNNEL AND PENSTOCK TESTS AT CHELAN STATION, WASHINGTON.

By Ellery R. Fosdick 1409

Discussion:

By W. A. HILL 1426

S. P. WING, J. N. BRADLEY, AND H. P. EVANS, JR. 1428

W. S. MERRILL 1436

ELLERY R. FOSDICK 1436

1953 PROPOSED IMPROVEMENT OF THE CAPE COD CANAL.

By E. C. Harwood 1440

Discussion:

By C. S. JARVIS 1476

GEORGE R. RICH 1477

E. C. HARWOOD 1482

1954 THE ENGINEER AND HIS CODE: ADDRESS AT THE ANNUAL CONVENTION, PORTLAND, OREGON, JULY 15, 1936.

By Daniel W. Mead 1483

ERRATA

Transactions, Vol. 96 (1932)

Page 62, Fig. 28(*b*), the equation, "$M = 10 \frac{(36)}{(14)} \frac{1}{5} = 13.2$", should read,

"$M = 10 \frac{(36)^2}{(14)^2} \frac{1}{5} = 13.2$".

Page 424, Equation (5), "$q = dv = KHv = \phi K \sqrt{1 - K H^{\frac{3}{2}}}$," should read, "$q = dv = KHv = \phi K \sqrt{1 - K} H^{\frac{3}{2}} \sqrt{2g}$."

Page 424, Fig. 17, "$H = d$", should read "$(H - d)$".

Page 425, Line 28, "45%", should read, "45°".

Page 426, Equation (10), "$g^2 = m^2\, 2gH^3 = \phi^2 K\, (1 - K)\, 2gH^3$", should read, "$q^2 = m^2\, 2gH^3 = \phi^2 K^2\, (1 - K)\, 2gH^3$."

Page 427, Line 12, for "The factor, 3" etc., read, "The factor, β", etc.

Page 427, Line 14, for "Equation (3)", read, "Equation (4)".

Page 428, Fig. 20, "Values of ζ", should read "Values of β".

Page 428, Third line from bottom, "(Fig. 22)", should read "(Fig. 23)".

Page 428, Second line from bottom "(Fig. 23)", should read "(Fig. 22)".

Page 429, Line 1, for "*abc′″*", read "*abc″*".

Page 430, Equation (23), "$\beta = \frac{1}{1 - \frac{d}{R_0}} \times \frac{1}{\log \frac{1 - d}{R_0}}$", should read,

"$\beta = \frac{\frac{d}{R_0}}{1 - \frac{d}{R_0}} \times \frac{1}{\log \left(1 - \frac{d}{R_0}\right)}$".

PAPERS AND REPORTS OF COMMITTEES PUBLISHED IN PROCEEDINGS, AM. SOC. C. E. AUGUST, 1935, TO MAY, 1936, INCLUSIVE, NOT PUBLISHED IN TRANSACTIONS VOL. 101

	Number of *Proceedings.*
A DIRECT METHOD OF MOMENT DISTRIBUTION. By **T. Y. Lin**	December, 1934
TAPERED STRUCTURAL MEMBERS: AN ANALYTICAL TREATMENT. By **Walter H. Weiskopf** and **John W. Pickworth**	October, 1935
INFLUENCE OF DIVERSION ON THE MISSISSIPPI AND ATCHAFALAYA RIVERS. By **E. F. Salisbury**	November, 1935
STABLE CHANNELS IN ERODIBLE MATERIAL. By **E. W. Lane**	November, 1935
TRUSS DEFLECTIONS: THE PANEL DEFLECTION METHOD. By **Louis H. Shoemaker**	November, 1935
LATERAL PILE-LOADING TESTS. By **Lawrence B. Feagin**	November, 1935
SEDIMENTATION IN QUIESCENT AND TURBULENT BASINS. By **J. J. Slade, Jr.**	December, 1935
WIND STRESSES IN REINFORCED CONCRETE ARCH BRIDGES. By **A. A. Eremin**	December, 1935
SUCCESSIVE ELIMINATION OF UNKNOWNS IN THE SLOPE DEFLECTION METHOD. By **John B. Wilbur**	December, 1935
REINFORCED CONCRETE MEMBERS UNDER DIRECT TENSION AND BENDING. By **D. B. Gumensky**	December, 1935
PROGRESS REPORT OF THE COMMITTEE OF THE IRRIGATION DIVISION ON THE CONSERVATION OF WATER	December, 1935*
TALL BUILDING FRAMES STUDIED BY MEANS OF MECHANICAL MODELS. By **Francis P. Witmer** and **Harry H. Bonner**	January, 1936
MODERN CONCEPTIONS OF THE MECHANICS OF FLUID TURBULENCE. By **Hunter Rouse**	January, 1936
COMPARISON OF SLUICE-GATE DISCHARGE IN MODEL AND PROTOTYPE. By **Fred William Blaisdell**	January, 1936
BEHAVIOR OF STATIONARY WIRE ROPES IN TENSION AND BENDING. By **Douglas M. Stewart**	February, 1936
VARIED FLOW IN OPEN CHANNELS OF ADVERSE SLOPE. By **Arthur E. Matzke**	February, 1936

WEIGHTS OF METAL IN STEEL TRUSSES

By J. A. L. Waddell,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Arthur M. Shaw, Joseph G. Shryock, Albert F. Reichmann, Robert W. Abbett, George C. Diehl, F. G. Jonah, Clarence D. Foight, A. H. Fuller, William E. Wilbur, W. N. Downey, J. R. Grant, Theron M. Ripley, T. Kennard Thomson, H. H. Allen, John Venable Hanna, and J. A. L. Waddell.

Synopsis

From the ten sets of curves in this paper a designer can read the ratio of the weight of metal in a truss (per linear foot) to the total vertical load (live, impact, and dead loads per linear foot) for which the truss is to be proportioned. They apply to simple truss, cantilever, and arch spans, for railways, highways, and combinations of both, designed either with carbon steel or with silicon steel.

Modifying formulas or data are given to cover uneconomic proportions. the use of high-alloy steels, and variations in the specified intensities of working tensile stress for carbon-steel structures. There are also four sets of curves showing total weights of metal per linear foot for various classes of bridges. These curves are inserted for the purpose of enabling the computer to determine his trial total load.

The paper concludes with a table indicating the results of the "spot-checking" of the percentage ratios, shown on the diagrams, by means of a score of spans for which the truss weights had previously been accurately determined. Only the last two of these cases were utilized in the preparation of the ratio curves; hence the others serve as an absolutely unbiased check on the accuracy of the diagrams.

Introduction

If a bridge computer were able (generally within a minute or so) to find by diagram, for spans of any reasonable length and for the usual types of

[1] Cons. Engr., New York, N. Y.

structure, the ratio of weight of metal per linear foot in a truss to the total vertical load per linear foot for which that truss is to be designed, he would be saved much time and trouble. The writer has attempted to supply that need by collating extensive office records accumulated in practice, and plotting them in the form of curves for the use of the designer.

The results obtained are sufficiently accurate for preparing preliminary estimates of cost and for determining dead loads. In fact, they are so accurate that, when properly modified for variations in the intensities of working tensile stress due to using design specifications other than those recommended by the writer,[2] it is probable that no recomputation will ever be necessary because of any serious discrepancy between the assumed and the calculated dead loads. It would be futile to attempt to attain greater accuracy, because each bridge of any importance has some special individuality of its own, tending to cause slight variations from the most accurate of any curves of weight-of-metal ratios that could be made. Furthermore, each designer has personal idiosyncracies that affect the weights of the trusses he computes, and there is quite a perceptible difference in the metal weights between structures which are truly first-class in every particular and those of only mediocre excellence, or those that have been "trimmed" to the limit.

EXTENT AND LIMITS OF THIS INVESTIGATION

It will be noted that Figs. 1 to 5 include simple truss spans, cantilevers of both Type *A* and Type *C* (Fig. 6), and arches; but they embrace neither suspension bridges nor bascule spans. A little thought will convince any one with experience in bridge designing that it would not be feasible to plot the last two types.

The curves cover trusses of both carbon steel and silicon steel; and formulas are given herein for converting values of the weights of metal for silicon steel to the corresponding weights for all feasible alloy steels, up to those having an elastic limit of 100 000 lb per sq in. They embody single-track and double-track railway bridges, modern highway bridges of 20-ft clear roadway without sidewalks (the cheapest legitimate type of structure), and those of 40-ft clear roadway with two 5-ft sidewalks (the most common dimensions for first-class structures). For any other cross-section of floor, the desired "percentage ratio" can be found by interpolation or extrapolation, remembering that, in establishing the equivalent total width of floor, the sum of the widths of the sidewalks must be divided by two.

In the preparation of Figs. 1 to 5, the live loads for railroad bridges were those identified as Class 60 in "Bridge Engineering,"[3] and those for highway bridges were taken from curves presented elsewhere by the writer.[4] It will be noted that only three standard live loads have been utilized.

In Figs. 1(*e*), 1(*f*), 3(*a*), and 5, the truss weights include the weight of the metal in the bents above the arch rings. The reason for inserting

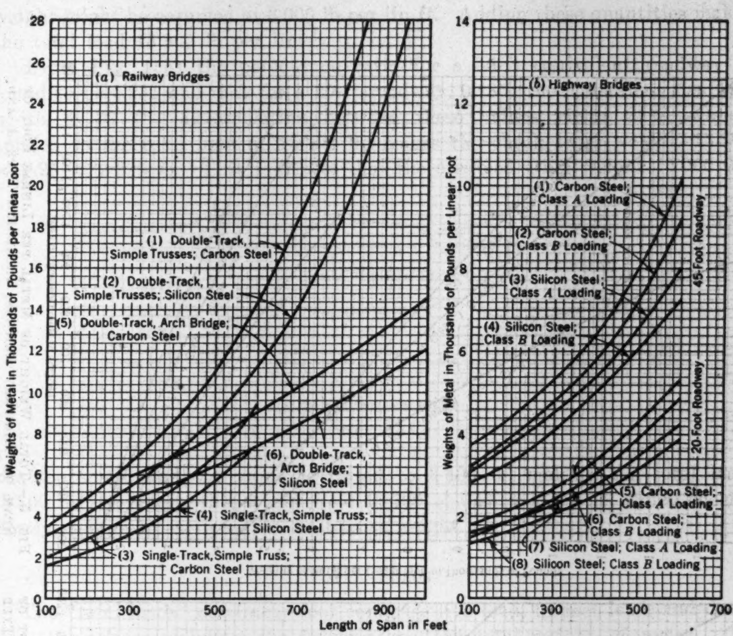

FIG. 3.—TOTAL WEIGHTS OF METAL PER LINEAR FOOT OF SPAN, IN ARCHES AND SIMPLE TRUSS SPANS.

Figs. 3(*a*), 3(*b*), 4, and 5 is to aid computers in finding the trial total load per linear foot for any proposed structure; after doing which the "percentage ratio" can be ascertained from one of the first ten diagrams and another trial made, if necessary.

EXAMPLE

As an example of how a computer would proceed with a new problem, consider the design of a 450-ft, simple-truss, highway span, with Class *A* loading, a 30-ft clear roadway, two 8-ft sidewalks, and trusses of silicon steel. The first step is to determine the character and weight per linear foot of the flooring for both roadway and sidewalks. Assume that this weight is found to be 4 300 lb. The next step is to determine the approximate weight of metal (generally carbon steel) in the floor system and hand-rails, as well as that in the lateral system, which should be of silicon steel. From a prepared table[5] the weight of metal in the floor system and hand-rails is found to be about 1 650 lb per lin ft, and that of the lateral system to be about 540 lb per lin ft. The live load would be found by proportion[6] to be 3 360 lb per lin ft, and the impact,[7] 13.3% of 3 360 or, say, 450 lb per lin ft. The truss

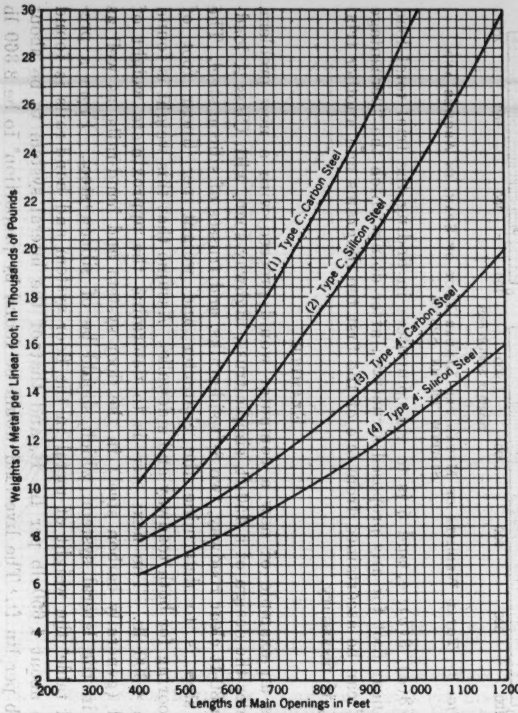

FIG. 4.—TOTAL WEIGHT OF METAL PER LINEAR FOOT OF SPAN, IN DOUBLE-TRACK, RAILWAY, TYPE *A* AND TYPE *C* CANTILEVER BRIDGES.

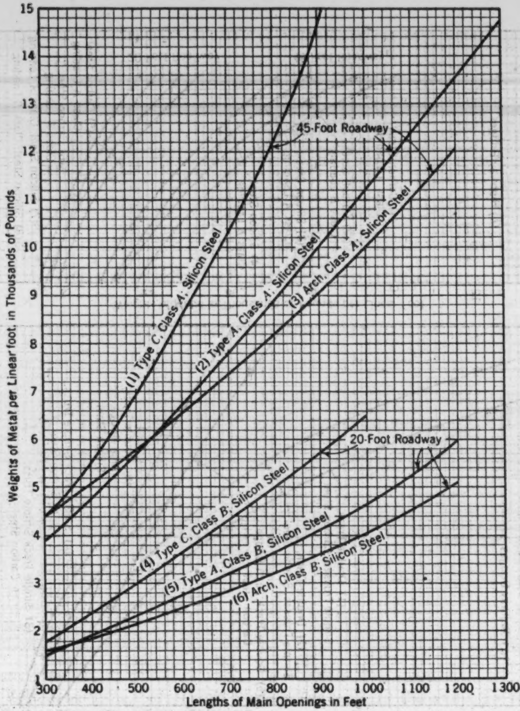

FIG. 5.—TOTAL WEIGHT OF METAL PER LINEAR FOOT OF SPAN, IN HIGHWAY BRIDGES, INCLUDING TYPE *A* AND TYPE *C* CANTILEVERS.

weight might be assumed at 3 000 lb per lin ft. Adding these quantities makes the total load 13 300 lb per lin ft.

From Fig. 1(*b*) the percentage ratio for a 45-ft equivalent roadway is found to be 0.237 and that for a 20-ft roadway, 0.285; the equivalent roadway width is 38 ft. Interpolation between these values yields 25%, which, applied to the total load of 13 300 lb, makes the check truss weight, 13 300 × 0.25 = 3 325 lb. This indicates that the assumed truss weight (3 000 lb) was too small, and the value is raised to 3 400 lb, making the total load 13 700 lb. As before, this would yield 13 700 × 0.25 = 3 425 lb, which checks closely enough to serve as the final truss weight.

(*b*) Type *C*, Cantilever Bridge

FIG. 6.

TOTAL LOADS

The "total loads" per linear foot comprise live load, impact load, and dead load, the latter including the flooring and the total weight of metal. Of course, the truss dead load excludes the metal on the piers or in the anchorages. In determining the equivalent uniform live load per linear foot and the corresponding impact load for any cantilever arm, the length of span to be used is the sum of the length of one cantilever arm and that of the suspended span. In finding the average uniform live load plus impact per linear foot for the entire structure, it is not correct to take the direct average for the three distinct parts of it; each value computed must be multiplied by the total length that it governs, the three results added, and the sum divided by the total length of structure. The same method is to apply to the finding of the average total truss load per linear foot, and of the average weight of truss metal per linear foot, for any cantilever bridge.

MODIFICATIONS OF WEIGHT-CURVE FINDINGS

In determining the weights of metal for the various curves, economic proportions of layout were assumed. If uneconomic designs must be utilized, the weights found from these curves will need modification, as shown in the text following.

Type C Cantilevers.—For greatest economy of metal, the length of the anchor span should be 0.36 times the total length of the structure. If the proportion differs from this, the average weight of truss metal per linear foot will have to be multiplied by one of the quantities given in Table 1.

TABLE 1.—MODIFICATION FACTORS FOR UNECONOMIC LAYOUTS OF TYPE *C* CANTILEVERS

Ratio of length of anchor span to total length of structure	Multiplier for weight given by diagram	Ratio of length of anchor span to total length of structure	Multiplier for weight given by diagram
0.31	1.10	0.35	1.01
0.32	1.08	0.36	1.00
0.33	1.06	0.37	1.05
0.34	1.04	0.38	1.19

Arch Bridges.—For the greatest economy of metal in two-hinged and three-hinged arch bridges the ratios of rise to span are as follows:

Solid-rib structures	0.175 to 0.225
Braced-rib structures	0.200 to 0.250
Spandrel-braced structures, with hinge above	0.225 to 0.275

For hingeless arches each of the foregoing values must be increased by 0.05. The variations in weights of metal in arches caused by the adoption of uneconomic ratios of rise to span length have never yet been determined. For this investigation it is not worth while to make special designs for a number of arch bridges in order to find them—especially in view of the fact that the economic ratio for any case has a fairly wide range (0.05), which is about 11% either above or below the average of the economic ratios.

Uneconomic Truss Depths.—The variations in weight of metal in simple trusses caused by the adoption of uneconomic truss depths almost invariably occur in deck spans, due to a restricted vertical distance between clearance line and grade; and, in these cases, parallel chords are always used.

The correcting ratio, r, is determined thus: Let w = weight of metal, in pounds per linear foot, for a truss of economic depth, d; and w' = weight for any other depth, d', less than d.

The weight, w, is about equally divided between the chords and the web; the chord weight varies almost inversely as the depth; and the web weight varies almost directly with the depth; hence,

$$w' = \frac{w}{2} \times \frac{d}{d'} + \frac{w}{2} \times \frac{d'}{d} \quad \text{.................... (1)}$$

and,

$$r = \frac{w'}{w} = \frac{1}{2}\left(\frac{d}{d'} + \frac{d'}{d}\right) \quad \text{.................... (2)}$$

WEIGHTS FOR ALLOY-STEEL TRUSSES

To find the weight of metal for any alloy-steel truss, with an elastic limit, s_y, all that is necessary is to ascertain from Figs. 1 to 5 the weight of truss metal for silicon steel, and multiply it by:

$0.3 + 0.7r$, for medium spans (less than 500 ft);

$0.25 + 0.75r$, for fairly long spans (500 ft to 1 000 ft); and

$0.2 + 0.8r$, for very long spans (more than 1 000 ft).

In the foregoing values, $r = \frac{45\,000}{s_y}$ (45 000 being the elastic limit for silicon steel). For example: What is the linear weight of truss metal in a simple-truss, double-track railway span of 500 ft, when an alloy steel of 70 000 lb elastic limit is utilized, the total load per linear foot being 25 000 lb for a silicon-steel bridge?

For a silicon-steel bridge, Fig. 1(*a*) yields a ratio of 0.272; therefore, the weight of truss steel is $0.272 \times 25\,000 = 6\,800$. Furthermore, $r = \frac{45\,000}{70\,000} = 0.643$; and $0.3 + 0.7r = 0.75$. Therefore, the weight required $= 6\,800 \times 0.75 = 5\,100$ lb.

ADAPTATION TO OTHER SPECIFICATIONS

The curves can be utilized for design specifications other than those of "Bridge Engineering," because the main factor in modifying the weight of metal is the comparative averages of the ratios of the principal intensities of working stresses in the two cases. The final average is almost exactly that of the two specified intensities of working tensile stress. The intensity specified in "Bridge Engineering" for carbon steel is 16 000 lb per sq in., and that for any more modern set of bridge specifications is likely to be greater—in most cases as much as 18 000 lb per sq in., and in extreme cases, 20 000 lb per sq in. If the new intensity is denoted by s_t, then $\frac{16\,000}{s_t}$ will be the value of the ratio, *r*.

If Figs. 1 to 5 indicate a weight, *w*, for the writer's specifications, the corresponding weight for the other specifications will be:

$w' = w\,(0.3 + 0.7r)$ for short spans (less than 500 ft);
$w' = w\,(0.25 + 0.75r)$ for medium spans (500 ft to 1 000 ft); and,
$w' = w\,(0.2 + 0.8r)$ for long spans (more than 1 000 ft).

For instance, if the intensity of tensile stress for carbon steel in the other specifications is 18 000 lb per sq in., for a span of medium length, *r* will be $\frac{16\,000}{18\,000} = 0.889$; and $w' = w\,(0.25 + 0.75 \times 0.889) = 0.917\,w$.

In addition to a double checking by the writer of all the calculations made for this paper, the curves have been "spot-checked" by his firm's office force through reference to recorded results of both actual and computed weights of metal, for structures engineered during the last two decades by both himself and his present firm; and the outcome of this spot-checking has been eminently satisfactory, as can be seen by reference to Table 2. As the last two cases were the only ones of this table used in preparing the first ten of the diagrams given herein, the other seventeen cases provide an unbiased check upon their reliability.

In the Portsmouth (N. H.) lift-span, for the sake of æsthetics, the chords were made parallel, whereas the top chords of the two flanking spans, of like length, are polygonal. The lack of economy in the parallel chords (see Column (11), Table 2) accounts for the pronounced variation between the computed ratio and the one found from the diagram. The Jacksonville (Fla.), the Tombigbee River, and the Cape Cod Canal Bridges were very carefully computed; but they have not yet (1935) been built.

* Number of tracks indicated for railway bridges.
† Average for two trusses of different live loadings in the same span.
‡ See reference to this item in the text.

The large variation recorded for the Springfield (Mass.) Bridge (Column (11), Table 2) is due to three causes:

(*a*) The bridge is a deck-span structure;
(*b*) The truss depth is only seven-tenths of the economic depth; and,
(*c*) The top chords of the four trusses carry, in bending, a portion of the flooring and its live load, each chord acting as one of the stringers.

Referring to the Charleston (S. C.) Bridges, all the values in Columns (8), (9), and (11), Table 2, were determined by the method previously outlined. The total loads, the weights of metal in trusses, and the computed "percentage ratios" are the averages for the total length of structure; that is, they cover the trusses of the suspended span, the two cantilever arms, and the two anchor arms of a Type *A* cantilever bridge.

A good idea of the accuracy of the "percentage ratios" given on the diagrams may be obtained from the following analysis of Table 2:

(*A*) The variations, regardless of plus or minus signs, between the computed and the diagrammed ratios, omitting from consideration the Portsmouth lift-span, average 0.4 per cent.

(*B*) The corresponding average of the variations, when the plus and minus signs are duly considered, is 0.3%—showing that, in general, the diagrams "under-run" by that amount. The cause of this under-run, undoubtedly, is that in a few cases the truss weights were somewhat greater than usual, owing to some slight abnormality in the governing conditions, whereas all the curves were determined, as closely as practicable, for truly economic structures.

When one considers all the causes that may affect the weight of metal in any truss, especially the unavoidable idiosyncrasies of bridge designers, an average variation of less than 0.5% in truss weights is very small indeed; and an extreme variation (unaccounted for) of less than 1.5% is by no means excessive.

A useful deduction can be drawn from the computations of the 264-ft span of the proposed Jacksonville Bridge. They were made for four cases—carbon steel, silicon steel, ordinary reinforced concrete flooring, and open-grating flooring. The corresponding truss weights were, respectively, 1 200, 900, 930, and 750 lb per lin ft, indicating a saving of metal from the lighter flooring of 22.5% in the trusses of the carbon-steel structure and one of 16.7% in those of the silicon-steel structure. There was also, of course, a further saving of metal in the floor system. From the sum of the money values of these two savings, in any case, must be deducted the extra cost of the flooring itself. In this case the showing favored the open-grating floor. The longer the span the greater is the net saving thereby; and it is evidently much more pronounced in carbon-steel structures than in silicon-steel structures.

DISCUSSION

Arthur M. Shaw,[*] M. Am. Soc. C. E. (by letter).—Methods for the quick determination of the weights of metal in bridge trusses are made available in this paper. The curves should effect a tremendous saving in time and effort which heretofore have been necessary in making preliminary studies of proposed structures. By the intelligent use of the graphs presented, it should be possible for the bridge designer to eliminate, promptly, several span-length combinations and types of trusses which, at first, might appear to be worthy of consideration.

Although the paper obviously is of primary importance to the bridge designer, the methods suggested may be used to great advantage by other engineers, especially those engaged in the location of railways and highways. In "easy" country, the locating engineer is not greatly concerned with the type of structure later to be adopted for crossing the various streams encountered. His main problems have to do with securing a reasonable alignment which will permit dropping, by an easy gradient, down to an elevation not far above flood level and at a point resulting in the least possible length of bridge and approaches. Although he gathers data regarding flood flow, navigation demands, and (perhaps) makes something of a study of foundation conditions, in general, his activities and interests are quite fully divorced from those of the designing engineer of the bridge department.

The situation is far different when locating a railway or a highway in a more rugged region. The engineer must have available for convenient use in the field the means of determining, with reasonable accuracy, the cost of various alternate types of structures of varying span lengths, if he is to secure "the best location which the country affords."

As a concrete illustration of the foregoing, the writer recalls a railway location survey which was made in Northern Mexico about 1906. Within a distance of less than thirty miles, the projected line crossed three large arroyos. One of these arroyos was nearly a mile wide, with adjoining topography which permitted easy development to a low crossing but, for the other two, there was no alternative between high viaducts of considerable length and low crossings involving excessively heavy work and objectionable alignment.

The line was constructed as originally located, with a low crossing of the first arroyo (which was obviously proper) and high crossings at the other two, although the writer is not yet satisfied that the most economical location was secured. A serious effort was made to balance the costs of alternate plans, and for this purpose, the engineer was furnished with a certain amount of assistance in the form of assumed cost data, but these data were of doubtful authenticity and were neither sufficiently flexible nor comprehensive. Had the material then been available, which the author has presented, the problems could have been studied intelligently, and it is reasonable to assume that a more economical location would have been secured.

---

[*] Cons. Engr., New Orleans, La.

The locating engineer has neither the time nor the facilities for making a careful analysis of alternate structures at each stream crossing, and, in many instances, he would not be competent to make such an analysis even under favorable circumstances; but with all the aids with which he may now be supplied, he should be able to estimate weights and costs with a degree of accuracy which will enable him to follow the true principles of economics. He probably will not select the type of bridge and the arrangement of span lengths which, later, will be found to be the most economical, but his line will be located so that the most economical crossing can be secured. He will have a sound basis for his decision, instead of founding it on a "hunch," or on personal bias, as has been done too often.

JOSEPH G. SHRYOCK,[9] M. AM. SOC. C. E. (by letter).—The bridge engineer should find this paper valuable because it gives him at once the percentage ratio of the weight of metal per linear foot of truss in terms of the known total dead load and live load for all usual spans and types.

As a matter of interest, the writer made a check with the author's tables on an actual highway bridge. The roadway width was 20 ft; it was designed with the *K*-type of truss, for *H*-20 loading; its span was 330 ft; and the unit stress for the conventional reinforced concrete floor was 18 000 lb per sq in. Table 1(*b*) shows a ratio of 23%, which, adjusted for the unit stress intensity, gives 20.4%, whereas a detailed estimate gave a ratio of 20%, which is remarkably close—a variation of only 0.4 per cent.

In the last paragraph of his paper, the author makes a comparison on the Jacksonville Bridge of the saving of 22.5% in the trusses by the use of an open-grating flooring in place of the ordinary reinforced concrete floor-slab. The writer made a comparative design and estimate, using a solid steel interlocking channel floor, with an asphalt plank wearing surface instead of the conventional concrete slab, on the aforementioned 330-ft highway bridge, which showed a saving of 22.6% in the carbon steel trusses, in addition to the saving of metal in the floor system. These combined savings more than offset the additional cost of the light-weight metal deck. As the spans increase, the actual savings in cost, of course, become more pronounced.

Some interesting bridges have recently been built by European engineers of chrome copper rustless steel, with physical properties comparable to silicon steel, and with a corrosion resistance four times that of the copper-bearing steel used in the United States. Recent developments in the metallurgy of steel and in the art of welding will doubtless play an important part in the design and construction of the great bridges of the future, and engineers in this country should watch with interest the remarkable progress being made in Europe.

ALBERT F. REICHMANN,[10] M. AM. SOC. C. E. (by letter).—Valuable data are offered in this paper, and the author has presented them in a convenient form which will enable a bridge computer or designer, readily and quickly, to secure the approximate weights of various types of trusses. This assembled information should be of great assistance in preparing preliminary estimates of cost and in determining preliminary dead loads. However, due to the many combinations of loading and the personal equation entering into a design, most engineers are reluctant to use weight curves to obtain dead load weights for final computations.

---

[9] Vice-Pres., Director, and Chf. Engr., Belmont Iron Works, Philadelphia, Pa

[10] Vice-Pres., Am. Bridge Co., Chicago, Ill.

In the collection of curves presented with this paper, the author has omitted the continuous type of truss span. This type of span has gained wide recognition in the past decade (1925–35), and has proved economical for long-span bridges. Curves covering the weight of continuous spans might well be added to those of the cantilever and arch spans. With this addition, a designing engineer would be able to determine the approximate weights of the different types of spans, and thus be able to make preliminary estimates and comparisons of cost of various types of spans more readily.

Mr. Waddell is to be commended for contributing to the Engineering Profession a useful set of weight curves. They should prove of distinct value to engineers engaged in making preliminary studies of different bridge projects.

ROBERT W. ABBETT,[11] ASSOC. M. AM. SOC. C. E. (by letter).—The greatest value of the data presented in this paper will be in the field of highway bridge design. Heretofore, several writers have developed formulas for the weights of metal in such structures, but the results from them vary over such a wide range that they are little better than guesswork. In general, the paper will be a distinct aid to younger engineers who have not yet developed the judgment required in preliminary bridge design.

Some pitfalls occur in the diagrams and their use should be tempered with reason. For example, the author states that,

> "* * * they [the results from the graphs] are so accurate that, when properly modified for variations in the intensities of working tensile stress due to using design specifications other than those recommended by the writer,[8] it is probable that no recomputation will ever be necessary because of any serious discrepancy between the assumed and the calculated dead loads."

This statement implies one conclusion that is dangerous, namely, that if there is no serious discrepancy between the assumed and the calculated dead loads no further consideration is necessary. The writer would like to call attention to the fact that both the assumed and the calculated dead loads are considered as being uniformly distributed over the span. In bridges having spans in the longer range included by the author the actual distribution of weight may become an important design consideration. This is particularly true in the case of the cantilever and arch types and to a lesser degree in long-span, curved-chord, simple trusses. Recomputation should always be made on the basis of the actual distribution of weight in the case of large and important structures.

---

[11] Asst. Prof. of Bldg. Constr., Thompson-Starrett Foundation, Dept. of Civ. Eng., Union Coll., Schenectady, N. Y.

In cases where concentrated live loads are specified, the practice in determining an equivalent uniform load is not standardized. The author recommends the following method for railroad truss bridges:[12]

> "If one will figure on cars preceding as well as following the locomotives and will compute the maximum moments at the quarter points of the spans, then substitute them for M in the proper formula ($M = \frac{3}{32} w l^2$), he will obtain the best averages for the equivalent load curves."

Presumably, the same procedure would be utilized for highway bridges in determining a uniform live load to be used with the diagrams.

Suspension bridges and bascule spans have been excluded from the scope of the investigation, and the author is correct in stating that it is not feasible to plot these types. Recognizing this fact, the diagrams provide a quick method for the preliminary design of all types of steel bridges with the exception of the simple-span, steel beam, the rigid frame, and the continuous truss.

The first two of these types are used for short spans and to estimate their weights is not an outstanding difficulty in design. The continuous truss, on the other hand, is becoming such an important type that it promises to replace the series of simple spans almost entirely, and perhaps the cantilever as well. If this is true there is a definite need for a diagram of weights for the continuous bridge similar to those presented in this paper.

George C. Diehl,[13] M. Am. Soc. C. E. (by letter).—The bridge engineer who has not had extensive experience and training is enabled, easily and quickly, to determine the most economical form of steel bridge construction, by the aid of this paper. Table 2 is especially interesting in showing the great accuracy of the charts which the author has prepared. The last paragraph of the paper is especially engaging, as it indicates the possibility of lighter floorings on highway bridges and shows how the open-grating floor will save in the trusses alone, one-fifth the cost if carbon steel is used, and one-sixth in case of silicon steel. Similar charts should be prepared which would show with equal facility and clearness the lessened cost of floor systems if the lighter floors were used and also the relative cost of the different types of floors.

In the United States the perils to life and limb, as well as the property damage, on the public highways are still on the increase. More than 36 000 deaths occurred in 1934, and nearly 1 000 000 people were injured. Many of these hazards occur by skidding on bridges. It is important, of course, that a bridge should be economical in its cost, but it is even more important that it should be safe horizontally as well as vertically. Safety from automobile accidents can be secured at lower cost. This applies particularly to new bridges. The lighter weight of open flooring makes its use practicable on existing structures, when it is found necessary to eliminate slippery roadways and to prevent accidents caused by ice and snow.

---

[12] "Bridge Engineering," by J. A. L. Waddell, M. Am. Soc. C. E., Vol I, p. 166.

[13] Cons. Engr., New York, N. Y.

A valuable addition to the paper would be a curve of relative cost of bridges with the conventional types of solid floor as contrasted with open, non-skid flooring.

F. G. JONAH,[14] M. AM. SOC. C. E. (by letter).—The paper offers in a condensed, workable form, a set of curves platted from information accumulated during years of practice and experience. The author is to be commended for his work of assembling and classifying these data and passing it on in a condensed graphical form to the Engineering Profession.

Figs. 1 to 5 will be of great value to bridge engineers (especially to those of less experience) in making preliminary studies and selecting economical types of design for proposed bridges. They will give bridge estimators reliable information that has not been available in such concise and workable form. The percentage-ratio weights of a number of the more recent carbon-steel, simple-truss railway trusses constructed on the "Frisco Lines" have been "spot"-checked and found to agree very closely with the curves of this paper.

CLARENCE D. FOIGHT,[15] M. AM. SOC. C. E. (by letter).—There is no doubt but that the author has made a valuable contribution to bridge designers. In using his curves, however, the designer should know the height ratio, the number of panels, and the type of diagonal bracing that have been used in the design of the bridges from which the curves were derived. Should the most economic height ratio for any span be known, there will be a difference in truss weight for different types of trusses, and for trusses of the same type having different numbers of panels. On a number of occasions, the writer has compared different types and variously proportioned simple-span trusses and has found that a comparison of several trusses having different numbers of panels and different height proportions is generally required before one is able to determine the most economic proportions.

Fig. 7 is a tool for such comparisons, which may help to explain discrepancies in truss weights derived from the author's empirical curves when the truss is not a truly economic structure.

The curves, applying to three common simple-span truss types, are referred to the rational formula,

$$w' = \frac{w_c \times 3.4\,(1 + p)\,L\,\dfrac{K}{n^2}}{f - 3.4\,(1 + p)\,L\,\dfrac{K}{n^2}} \dots\dots\dots\dots\dots\dots (3)$$

in which w' = average weight of metal per linear foot of truss (not including the members in Fig. 7 which are shown dotted); w_c = average weight per linear foot, carried by truss (includes floor system, all bracing, railing, uniform live load, uniform live load equivalent to a concentration of load, and impact); p = ratio of details to gross section; f = average allowable fiber stress in gross section; and L = span length. Equation (3) can be relied upon to give the truss weight to an accuracy of within 5 per cent.

---

[14] Chf. Engr., Frisco Lines, St. Louis, Mo.

[15] Foundation Designer, Jones & Laughlin Steel Corp., South Side Works, Pittsburgh, Pa.

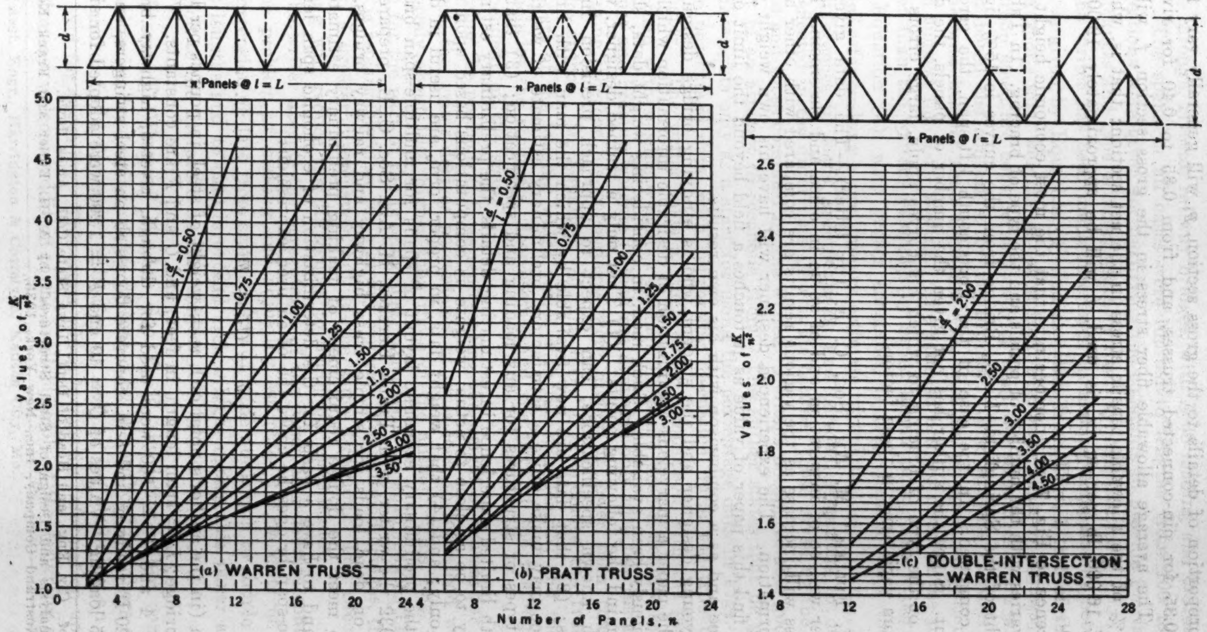

FIG. 7.—COEFFICIENT CURVES.

The proportion of details to the gross section, p, will generally vary from 0.30 to 0.35 for pin-connected trusses, and from 0.35 to 0.40 for riveted trusses. The average allowable fiber stress in the gross section, f, will be about 75% of the allowable tensile stress in the net section; that is, when a stress of 16 000 lb per sq in. is used, f will be approximately 12 000 lb per sq in.

Reference to Fig. 7 will demonstrate that the most economic height proportion varies with the number of panels and the type of bracing. In Table 2, the weight of the Springfield, Mass., Bridge from the curves is 15% lighter than as computed. In the case of the Portsmouth lift-span, the error is 8 per cent. Since the author has not given the number of panels, the depth of truss, or the type of bracing to which his curves apply, large errors may result from variations in these factors.

A. H. FULLER,[16] M. AM. SOC. C. E. (by letter).—The data given in this paper will be of inspiration and of value in office and classroom. Their usefulness will increase as the various results are compared with other available information. The experienced designer will have his own weight data, and will find this paper of value as it touches a field beyond the limit of his experience and as a comparison with his own results.

The young designer and the student who is studying bridge design will find in the paper a marvelous organization of desirable information which has not previously been available. Such men, in considering weight data, should keep in mind the following points: (1) That only a trained designer, working with known specifications, can expect to approach precision in his estimates; (2) that data are now available by which the man with limited experience may make quite a satisfactory preliminary estimate of weight of various types of structures for any loading and specification; (3) that, for those with limited experience in estimating details, the preliminary estimates are likely to be as close to actual weights as computations based upon main sections only; and (4) that weight data, in proper form, are useful in determining the preliminary economic layout of spans for multiple-span bridges.

In 1932 the writer, with Frank Kerekes, M. Am. Soc. C. E., prepared an article[17] on dead loads for simple truss highway and railway bridges. In order to meet the double requirement of making preliminary estimates of weight and to have a basis for the determination of economic span lengths of simple-span bridges he chose the often used expression:

$$w = CL + F \quad \text{..........................(4)}$$

in which (in the author's notation), w = weight of steel, in pounds per linear foot of bridge; L = span length, in feet; and C and F are constants. Values of $C = 4$ and $F = 500$ were used for through, riveted, highway bridges with a 20-ft roadway and 8-in. concrete floor-slab on steel stringers, and for the H-15 loading. Values of $C = 10$ and $F = 1\,200$ were adopted for single-track, through, riveted, railway bridges, with E-60 loading and ordinary open floor. The spans in all cases were limited to lengths from 100 to 300 ft. Suggestions were given for modifying the constants to provide for variations in thickness and type of floor, width of roadway, and live load.

---

[16] Prof., Civ. Eng., and Head of Dept., Iowa State Coll., Ames, Iowa.

[17] "Analysis and Design of Steel Structures", by A. H. Fuller and Frank Kerekes, D. Van Nostrand Company, Inc., New York, 1933.

The writer has been much interested in making comparisons between results as given by Equation (4) and as taken from Figs. 1 to 5 of the paper. The author's total weights, as taken from Fig. 3 for Class B highway bridges of carbon steel, are considerably heavier than the structures upon which the writer based the constants for his formula. The author's Class A bridges are likewise heavier than Equation (4), with its proposed reduction factor, would suggest for H-20 loading. The railroad bridges cited in the paper are lighter than the writer's examples by about 10 per cent. The writer believes that Equation (4), with proper constants, is more flexible than the curves in Fig. 3 for making a preliminary estimate of weight.

Differences in loads, specifications, and personal equations in designers, are reflected in the differences in weights between those given by the author's curves and those compiled by the writer. Perhaps no appreciable good would result in an attempt to reconcile them. The author states that he gives the actual weights only as a start for using the percentage data in Figs. 1 and 2. These percentage data, with supporting discussion, form the true basis for the paper. The writer finds a much closer comparison with the percentage data than with specific weights. In fact, he would need a definite separation of truss and bracing weights (which are available only in a few instances) to determine whether his percentages were higher or lower than those given by the author. In Equation (4), the term, $C L$, includes the trusses and that part of the bracing which varies with the span length; and the factor, F, includes the stringers, floor-beams, and the part of the bracing that is independent of the span.

Using the product, $C L$, as representing the weight of trusses for highway bridges, the writer derives percentages of truss load to total load which are uniformly about 10% higher than those of the author. This 10% is a fair value for the part of the bracing that varies with the span length. The check, then, is remarkably close for highway bridges. For railroad bridges, the writer found a greater discrepancy, but in the same direction. The effect of the bracing will reduce the differences to negligible magnitudes.

The writer accepts the percentages of the paper as a definite contribution to the problem of making and adjusting estimates for weights of bridges. The extension of data from simple spans of moderate length to simple spans of great lengths and to cantilever and arch bridges makes this paper a notable addition to the literature on this subject.

William E. Wilbur,[18] M. Am. Soc. C. E. (by letter).—For some years the writer has been using curves presented by the author,[8] or others similarly constructed, for preliminary estimates, as well as for obtaining an assumed dead load for designing. This paper which brings the information up to date, constitutes a welcome addition to the available tools of the designing engineer.

---

[18] Asst. Engr., Harrington & Cortelyou, Kansas City, Mo.

The device of expressing the weight of the truss as a percentage of the total load results in a considerable simplification of the diagrams. The process could readily have been carried one step further, by expressing the truss weight as a percentage of the superimposed load; that is, the total load exclusive of the weight of truss. When this is done, the weight of the truss is obtained directly, without the necessity of first assuming its weight before entering the diagram, as was done in the example given by the author. In Fig. 8, the author's diagrams, Fig. 1(*c*) and Fig. 1(*d*), giving weights of simple trusses of carbon and silicon steel, have been replotted on this basis.

The weights given in the paper agree quite closely with the experience of the writer. Assuming the same basic unit stresses, the minor differences of specifications will have no great effect on the weights of properly designed trusses. For ordinary highway bridges of carbon steel and moderate span, with a basic unit stress of 16 000 lb per sq in., the writer has found the following formula quite satisfactory:

$$w = \frac{1}{2} L + \frac{w_t L}{1\,600} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

in which (conforming to the notation of the paper), w = weight of truss, in pounds per linear foot; L = span length, in feet; and w_t = load on one truss, including weight of truss, in pounds per linear foot. In terms of the plotting used by the author (Fig. 1(*c*)), this gives a straight-line variation. The author's lines are slightly curved, which is more accurate for the longer spans and heavier loadings.

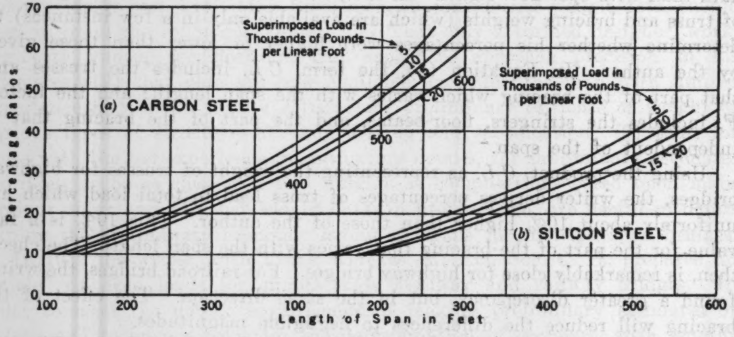

FIG. 8.—PERCENTAGE RATIOS OF WEIGHTS OF METAL FOR SIMPLE BRIDGE TRUSSES IN GENERAL.

Attention should be called to the fact that the loads per foot, given in the author's diagrams, are the total for two trusses, rather than for one truss. The minimum given, 10 000 lb per ft, is rather too heavy for short, light spans. For highway bridges of 20-ft roadway with concrete floor, designed by specifications for *H*-15 loading, advanced by the American Association of State Highway Officials, the total load per foot of span for short spans is only slightly more than 5 000 lb.

In his previous paper on "Economic Proportions and Weights of Modern Highway Cantilever Bridges,"[19] the author gave, for structures of combined silicon and carbon steel, an estimate of the percentage of each kind of steel in the structure. This information is of great value in making preliminary estimates; and the writer would suggest that the value of the paper will be considerably increased if the author will include, in his closing discussion, such data for the structures covered in this paper.

W. N. DOWNEY,[20] **ASSOC. M. AM. SOC. C. E. (by letter).**—The Engineering Profession is indebted to the author for considerable information concerning the weights of metal in bridges; his paper is a notable contribution, covering as it does such a variety of types. The following discussion is restricted to comments on the author's weights of simple-span highway bridges. The curves submitted for comparison with Figs. 1 to 5 were designed to carry live loads and impact loads in accordance with the recommendations of the American Association of State Highway Officials (1931). The allowable unit stress in tension was taken at 16 000 lb per sq in. on the net section except where noted. The designs provided for a concrete floor and a future surface item, the combined weight of which was 115 lb per sq ft of floor area.

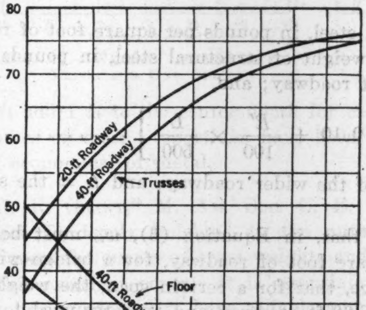

FIG. 9.— DISTRIBUTION OF METAL.

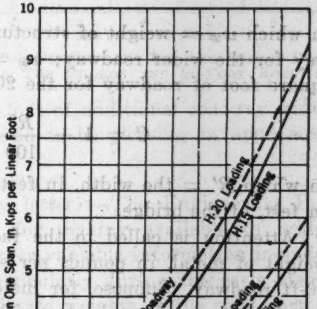

FIG. 10.—TOTAL WEIGHTS OF METAL. (1 KIP = 1 000 POUNDS.)

---

[19] *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 888.

[20] Louisville, Tenn.

The writer obtained a close check on the percentage ratios of Fig. 1(*b*), his values being about 1% higher than the ratios shown by the author. This is gratifying since it gives a check on the portion of the bridge weight that is most difficult to estimate, namely, the trusses. In this connection, Fig. 9 shows the distribution of the metal between the major elements of the span. The weights of hand-rails, expansion devices, and shoes are not included in the weights given in the paper.

Presumably, the total weights of metal given by Fig. 3 (*b*) include the weights of the hand-rails and expansion dams. The total weights obtained by the writer for bridges with 20-ft roadway, are in good agreement with Fig. 3(*b*) for the longer spans, but he gets somewhat smaller weights for spans of less than 300 ft.

Frequently, one has available the weight of metal in a bridge of a certain span length and roadway width, but desires the weight of metal for another bridge of the same span having a different roadway width. From a study of data at hand the relation expressed by Equation (6) was found to give good results. The weight of metal may be determined for any wider roadway from the weight for a 20-ft roadway by the following equations:

$$w_w = C\, w_{20} \qquad \text{(6)}$$

in which w_w = weight of structural steel, in pounds per square foot of roadway for the wider roadway; w_{20} = weight of structural steel, in pounds per square foot of roadway for the 20-ft roadway; and,

$$C = 1 - \frac{R'}{100}\left[0.10 + \frac{R'}{100} \times \frac{L}{500}\right] \qquad \text{(7)}$$

in which R' = the width, in feet, of the wider roadway; and L = the span, in feet, of the bridge.

Attention is called to the fact that, in Equation (6), w_{20} must be the weight of metal, in pounds per square foot of roadway, for a bridge with a 20-ft roadway. Suppose, for instance, that for a certain span, the weight of metal is known for a bridge with a 30-ft roadway and it is required to find the weight for a bridge having a 40-ft roadway. First, using Equations (6) and (7) and the known weight, w_w, for the 30-ft roadway, compute the weight, w_{20}, for a 20-ft roadway bridge. Then, with the value of w_{20} known, apply Equations (6) and (7) again to find the weight of metal, in pounds per square foot, in the bridge with a 40-ft roadway.

Fig. 10 shows the total weights of metal in the spans as determined by the writer and is included for comparison with the values given in Fig. 3(*b*). Fig. 11 permits the determination of desirable values that are not directly determinable by Figs. 1 to 5 of the paper. It yields the weights of the floor system and, incidentally, shows the effect on the floor weight of changing the panel length.

As is demonstrated in the paper, the depth of truss affects its weight materially. Coefficients for the determination of the truss depths for bridges with 20-ft roadways may be read from Fig. 12. For roadways wider than

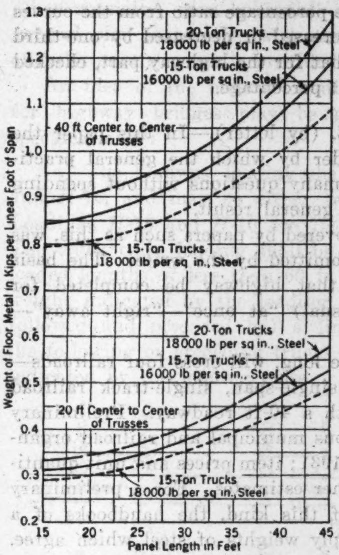

FIG. 11.—WEIGHT OF METAL IN FLOOR FOR ONE SPAN.

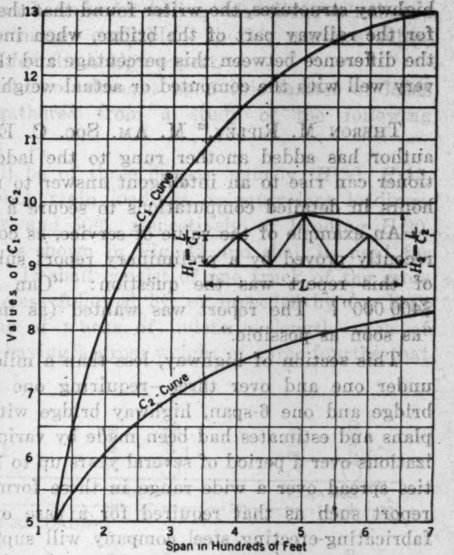

FIG. 12.—DEPTHS OF TRUSSES WITH POLYGONAL TOP CHORDS AND 20-FOOT ROADWAY.

20 ft add 1 ft to the center depth for each 5 ft of additional roadway width. Trusses of these proportions have been found to be pleasing in appearance and economical of metal.

J. R. GRANT,[21] M. AM. SOC. C. E. (by letter).—The Engineering Profession is deeply indebted to the author for making available to bridge engineers the curves of truss weights and other valuable information included in this excellent paper. It is essential, particularly during the early stages of a bridge project, to have reliable approximate weights of the steel part of the structure on which to base estimates of the cost of alternative plans. The floor can be computed quickly and the bracing can be estimated, so that with the truss weights readily available from the curves, an approximate estimate of the weight of steel in the superstructure is soon obtained.

The writer checked some of the percentages given by Figs. 1 to 5 for a number of spans for which he had the weights available, and although there was considerable variation in some cases it was usually not difficult to account for the difference between the computed percentage ratio and that from the curves. They should enable any bridge engineer, who is familiar with the design of the class of structure proposed, to make a fairly close estimate of the truss weights. It is essential that due allowance be made for the various factors, besides unit stresses and variation from the economic depth, which will have an influence on these weights. In considering combined railway and highway structures, the writer found that the percentage ratio from the curves for the railway part of the bridge, when increased or decreased by one-third the difference between this percentage and that for the highway part, checked very well with the computed or actual weight percentage.

---

[21] Structural Engr., Vancouver, B. C., Canada.

Theron M. Ripley,[22] M. Am. Soc. C. E. (by letter).—In this paper the author has added another rung to the ladder by which the general practitioner can rise to an intelligent answer to many questions without spending hours in detailed computations to secure a general result.

An example of the value of service, as covered by papers such as this, was recently proved by a preliminary report submitted by the writer. The basis of this report was the question: "Can that highway be completed for $400 000"? The report was wanted (as usual) "at once"—"right away"—"as soon as possible."

This section of highway, less than a mile long, will cross four railroads—under one and over three—requiring one single-span, single-track railroad bridge and one 6-span, highway bridge with a 40-ft roadway. Preliminary plans and estimates had been made by various municipal and railroad organizations over a period of several years up to 1931; item prices and unit quantities spread over a wide range in these former estimates. For a preliminary report such as that required for a case of this kind, the handbooks of a fabricating-erecting steel company will supply weights of steel which agree, with sufficient accuracy, with the weights determined by Fig. 3 of the paper.

This question of "loads" for highway bridges has become of greater importance as the class of traffic has changed. Live loads (moving loads) have increased from an average maximum, say, of 4 tons per unit to an average maximum of 20 tons. or more, per unit; and speeds have increased from 3 to 25 miles per hr, with impact "entering the picture" in a geometrical ratio.

At the beginning of the Twentieth Century, the sale of small bridges identified as "town-bought-bridge-company-competitive" designs, was a "racket" in the State of New York. Structures were sold, not necessarily to the lowest bidder, or to the most reliable firm, but to the most generous payer. As the entire cost must come out of the bridge, the keen competition for work on the part of the bridge companies, and for money on the part of the buyers, created a situation in which the steel in the structure became of minor importance.

Another type of this class of bridge, was the so-called "bedstead design," found principally in the mountainous regions. It was composed of white-painted railings of 1-in. and $1\frac{1}{2}$-in. pipe, and resembled nothing so much as the white iron bedstead found in mountain inns.

The flimsy, spider-web trusses of these bridges are no longer considered "good business" as damage claims are difficult to contest and expensive to settle. The bridge engineer has come into his own on highway bridges of practically all lengths and it is with information such as that supplied in this paper that the engineer who has devoted his time to hydraulics, or some other specialty, may be saved much time in telling his client whether a general plan is possible with the money available. In this manner, subsequently, another case is provided for the bridge expert.

---

[22] Cons. Engr., Buffalo, N. Y.

An idea of the present condition of thought upon this matter of loads for highway bridges may be gathered from a study of the following specifications[33]:

(*a*) The highway loading shall be of three classes, namely, *H*-20, *H*-15, and *H*-10, and may be either truck train loadings or equivalent loadings. Loadings *H*-15 and *H*-10 are 75% and 50%, respectively, of Loading *H*-20. The truck train loading shall be as shown in Fig. 13 and shall be used for loaded lengths of less than 60 ft. It shall consist of one truck of the gross weight indicated by the loading class followed by, or preceded by (or both followed and preceded by) a line of trucks of indefinite length, each of the following or preceding trucks having a gross weight of three-fourths that indicated by the loading class.

FIG. 13.—SPECIFIED TRUCK TRAIN LOADING (1 KIP = 1 000 POUNDS).

(*b*) If the loaded width of the roadway exceeds 18 ft, the specified loads shall be reduced 1% for each foot of loaded roadway width in excess of 18 ft, with a maximum reduction of 25 per cent.

The *H*-20 loading referred to in Specification (*a*) is shown in Fig. 13. Loadings *H*-15 and *H*-10 differ only in the applied loads, the spacing of trucks being the same for all classes. Specification (*b*) indicates the permissible reduction in "load intensity." If the author has used the *H*-15 and *H*-10 loadings as his Class *A* and Class *B* loadings (which is what they are termed in the Standard Specifications[33]), it is believed that his paper is not consistent with present practice in the Engineering Departments of the State of New York. As far as the writer can learn this State is designing, and approving the design of, bridges under Class *H*-20 loadings and using 20 ft as the distance between trucks.

---

[33] Standard Specifications for Highway Bridges and Incidental Structures, by the Am. Assoc. of State Highway Officials, 1931; Specifications 5.2.7, p. 174, and 5.2.10, Fig. 5, p. 176.

Highway bridges are now being built with 40-ft roadways, consisting of reinforced concrete pavements 12 in. thick and, where they cross a railroad, the steel floor systems are cement-coated. Under such construction the dead weight of reinforced concrete per linear foot of bridge, is about 3.83 tons; to carry this concrete the floor system will weigh about 0.54 ton per lin ft of bridge. Adding impact loads, wind pressure, or the weights of curbs, sidewalks, snow, pipe lines, etc., indicates a wide departure from the spider-web type of truss.

Loadings for highway bridges present an open question at the present time. Various types of steel floors are being studied in order to reduce the tremendous weights of solid concrete or block pavement. Live loads are pure assumption based, perhaps, upon the hope that the bridge will endure even if the truck operator insists on transporting all the freight in the country in unregulated loads and at, practically, unregulated speeds.

As a large majority of the bridges being built upon highways (those carrying the obstruction over the highway as well as those carrying the highway over the obstruction) are of 300 ft, or less, in span length, it is hoped that the author will describe somewhat in more detail loadings and other factors that affect Figs. 1 to 5. The final design must always be made by the bridge engineer, as guessing and "skinning" are ruled out when dealing with present-day, and probable future, traffic weights, volumes, and speeds.

T. Kennard Thomson,[24] M. Am. Soc. C. E. (by letter).—Recalling vividly an experience of more than forty years ago, the writer does not hesitate to state that, had it been available, this paper would have been worth considerable money to him in times past. He had been assigned, suddenly, the task of designing and estimating the cost of a bridge over the East River in New York City, to be composed of six tracks, two roadways, and two sidewalks. The maximum time allotted to the task was one week.

The only truss bridge of comparable length at that time was the Firth of Forth Bridge in Scotland which had been described[25] by the late Sir Benjamin Baker, Hon. M. Am. Soc. C. E. Designing the floor system carefully and the lateral system proportionally, the writer used the dead-load weights of the Forth Bridge in solving the stresses for the bridge graphically. By successive repetitions of this procedure a schedule of dead loads was determined which seemed satisfactory.

Four bridge companies were requested to check the design and the quantities, and the only organization that could be interested required the services of a squad of men for four months to produce the complete design.

The foregoing account demonstrates roughly, the tremendous amount of time that can be saved by the use of curves, such as those in the paper. Even in those days, the designer had at least one standard handbook, produced by steel manufacturers. They had an infinitely easier job than the late James B. Eads, F. Am. Soc. C. E., for example, who had to invent his own structural shapes and fight to have them rolled.

---

[24] Cons. Engr., New York, N. Y.

[25] "Bridging the Firth of Forth," by Sir Benjamin Baker, Lond., 1887.

The paper is the result of such tremendous amount of strenuous and careful work, that all bridge designers to whom it is made available should be grateful for its presentation.

H. H. ALLEN,[26] M. AM. SOC. C. E. (by letter).—The results of the studies and investigations reported in this paper are borne out remarkably well by the extensive office records available to the writer. He has used the nine Type *A* cantilever bridges which he (with Wilson T. Ballard, M. Am. Soc. C. E.) presented in the discussion of the author's paper entitled "Economic Proportions of Weights of Modern Highway Cantilever Bridges,"[27] as a basis for the data submitted herewith, and, in addition, one other Type *A* cantilever bridge designed and constructed by the writer's firm, namely, the cantilever bridge across the Kanawha River, at St. Albans, W. Va.

Table 3 is an arrangement of these ten Type *A* cantilever bridges in a manner similar to Table 2 of the paper. In addition, Table 3 contains similarly arranged data for the suspended spans of the Type *A* cantilevers. Data for four simple spans are also included, namely, the 156-ft simple spans that form the approaches at each end of the cantilever bridge across the Ohio River, at Ashland, Ky.; the 144-ft simple approach span to the cantilever bridge across the Ohio River, at Huntington, W. Va.; the 300-ft lift span of the James River Bridge, at Newport News, Va.; and the 208-ft approach spans of the same bridge.

All the Type *A* cantilever bridges, except the one at Ashland, Ky., were designed for the use of medium structural grade steel with a basic working stress of 18 000 lb per sq in. The Ashland Bridge was designed for the use of silicon steel and heat-treated eye-bars in the main members of the trusses, with a basic working stress of 24 000 lb per sq in.

The percentage ratios in Table 3 (Columns (10) and (11)) are based on an adjustment in the weight of the trusses, as described in the author's paper, in order properly to evaluate the truss weights on the basis of a working stress of 16 000 lb per sq in. instead of the 18 000 lb per sq in. used. The computed percentage ratios for the ten cantilever bridges agree very closely with those taken from Figs. 1, 2, 3, and 5. All these computed ratios are higher than those taken from the plotted curves, except the cantilever bridge at St. Albans, W. Va., which is 2.7% lower. This can be explained as being due to the use of rolled sections throughout the trusses for this bridge, thereby reducing the weights of details in the trusses materially.

The larger variations between the percentage ratios computed and taken from the curves of the paper for the nine suspended spans can be explained by the additional erection material included in the weights of the trusses for these spans, as compared with the weights of similar simple spans erected on falsework. The close agreement between the computed percentage ratios and those taken from Figs. 1 to 5 for the four simple spans listed, is remarkable.

* Including electric street railway.

† 1 kip = 1 000 lb.

It will be noted, however, that in each case the computed percentage of truss weights is slightly higher than that taken from the curves, except in the case of the 208-ft James River spans for which the computed percentage ratio is 0.1% less than the ratio taken from the curves. This truss is of the Warren type with the intermediate posts omitted, which may explain the reduction in truss weights.

The fact that the computed percentage ratios are uniformly higher than those taken from the curves led to a further investigation by the writer. Fig. 14 shows the ratio of truss weights to total weight carried for simple highway trusses on which are plotted Curves *A*, *B*, and *C*, corresponding to Curves 1, 2, and 3, Fig. 1(*b*). The curves shown in dashed lines on Fig. 14, immediately above Curves *A* and *B*, respectively, are plotted by collating office records which include the weights of steel subdivided into floor, bracing, and trusses for ideal typical simple highway spans for Class *A* loading, varying by 50 ft in length from 200 ft to 500 ft, for roadway widths varying between 16 and 36 ft by 4-ft variations, with additional weights for one or two sidewalks of 6 ft, 8 ft, or 10 ft. The curves of Fig. 14, shown in dashed lines, were obtained by using the percentage of truss weights of these typical, ideal, highway, simple-truss spans compared with the total weight of these spans, and agree more closely with the computed percentage ratios in Table 3 than those of the paper. This may be attributed to the personal equation of the designer, as expressed by the author:

"* * * each designer has personal idiosyncrasies that affect the weights of trusses he computes, and there is quite a perceptible difference in the metal weights between structures which are truly first-class in every particular and those of only mediocre excellence, or those that have been 'trimmed' to the limit."

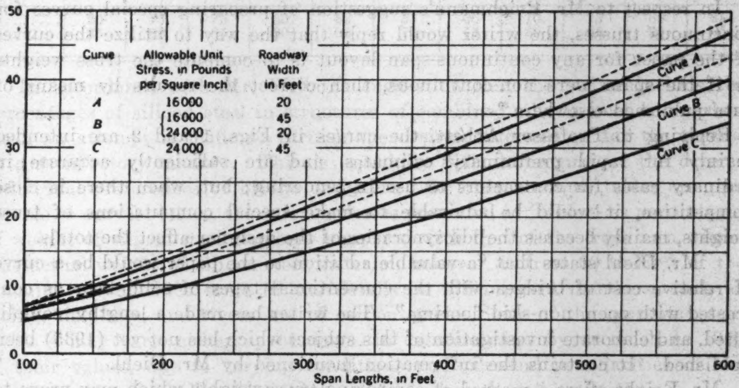

FIG. 14.—RATIO OF TRUSS WEIGHTS TO TOTAL WEIGHT CARRIED, SIMPLE HIGHWAY TRUSSES.

Regardless of the relatively small differences obtained from the results of the author's investigations and the data submitted by the writer, the writer feels that this method of approaching the problem of quickly estimating the weights of various types of trusses is an excellent one. These curves, of course, will need to be somewhat modified where the use of rolled sections reduces the weight of truss details.

JOHN VENABLE HANNA,[29] M. AM. SOC. C. E. (by letter).—In the early days of the Kansas City Terminal Railway Company's project for a new Union Station, and trackage in connection therewith, the writer was under the necessity of making, quickly, preliminary estimates of cost for a considerable number of structures. These structures were to carry urban highway traffic as well as railway traffic. In addition to the Union Station Building and the trackage immediately required for it, additional approach tracks were needed, which it was thought highly desirable should be entirely free from grade crossings. To estimate the cost of the structures necessary for this purpose, it was essential to determine weights of steel with a reasonable approach to the actual weights resulting from detailed designs. A method of estimating these weights, such as that set forth in the author's paper, would have been most welcome.

---

[29] Chf. Engr., Kansas City Terminal Ry., Kansas City, Mo. Mr. Hanna died on April 30, 1935.

No doubt many engineers have been in the position of needing reliable methods of estimating weights quickly, and many will be in that position hereafter. In the light of the writer's experience, he believes that this paper will be of great value to many members of the profession.

J. A. L. WADDELL,[29] M. AM. SOC. C. E. (by letter).—The two exceedingly close checks of the writer's findings reported by Mr. Shryock are very gratifying; and his allusion to the European chrome-copper rustless steel, having a corrosion resistance four times as great as that of the copper-bearing steel used in the United States, is both important and timely.

In respect to Mr. Reichmann's suggestion of preparing special curves for continuous trusses, the writer would reply that the way to utilize the curves of the paper for any continuous-span layout is to compute the truss weights as if the spans were non-continuous, then correct the results by means of data published elsewhere.[30]

Replying to Professor Abbett, the curves in Figs. 1 and 2 are intended mainly for rapid preliminary estimates, and are sufficiently accurate in ordinary cases for contractors to use in tendering; but, when there is close competition, it would be advisable to make special computations of truss weights, mainly because the idiosyncrasies of the designer affect the totals.

Mr. Diehl states that "a valuable addition to the paper would be a curve of relative cost of bridges with the conventional types of solid floor as contrasted with open, non-skid flooring." The writer has made a lengthy, complicated, and elaborate investigation of this subject which has not yet (1935) been published. It contains the information mentioned by Mr. Diehl.

Mr. Foight offers a method of comparing truss weights which may prove to be a bit misleading to some readers, causing them to think that the curves are greatly in error. The "percentages" treated in the paper are those of truss weights compared with total vertical loads; hence, the variation in the Springfield Bridge is 2.1% — not 15 per cent. That variation is entirely due to an uneconomic truss depth. As modern highway bridges are generally designed with economic panel lengths and economic truss depths, no "large errors" can "result from variations in these factors."

Professor Fuller's four cautions to "the young designer and the student who is studying bridge design" are directly to the point, and should be given thorough consideration by all tyros in such work. The writer has never had much luck in determining weights of metal in bridges by formulas, although for half a century he has been using quite freely various "formulas of reduction" of his own in passing from known weights of metal for certain conditions to the corresponding weights for differing conditions.

Replying to Mr. Wilbur, the writer deemed it more logical to make his percentage ratios apply to the grand total vertical load than to that load, less the truss weight; but Mr. Wilbur's supplementary diagrams, based on his assumption of omitting the truss weight itself, are most acceptable. He is correct in stating that it would have been better in Fig. 1 (*c*) and Fig. 1 (*d*) to add to each a curve for a total load of 5 000 lb per lin ft — in truth, the writer has since discovered this fact and has plotted such curves to aid in his own subsequent work. This is a case in which "one's hindsight is better than his foresight."

[29] Cons. Engr., New York, N. Y.

[30] "Economics of Bridgework", by J. A. L. Waddell, M. Am. Soc. C. E., Chapter XI.

TABLE 4.—APPROXIMATE AVERAGE PERCENTAGES OF SILICON STEEL MEMBERS IN TRUSSES OF COMBINED SILICON STEEL AND CARBON STEEL.

Roadway width (clear span), in feet	(*a*) PERCENTAGES IN SIMPLE TRUSS BRIDGES, FOR THE FOLLOWING SPAN LENGTHS, IN FEET:					(*b*) PERCENTAGES IN TYPE A CANTILEVER BRIDGES FOR THE FOLLOWING MAIN SPAN LENGTHS, IN FEET:					
	200	300	400	500	600	500	600	700	800	1 000	1 200
20.......	20	70	75	80	82	55	65	70	75	80	85
45.......	35	80	85	90	92	70	75	80	85	90	95

In accordance with Mr. Wilbur's suggestion that the writer include the percentages of silicon steel in structures of combined silicon steel and carbon steel, an attempt is made to furnish the desired information for the trusses in a satisfactory manner. This is especially difficult because of the diverse individual preferences of bridge designers. On that account, tables are preferable to curves; hence, the information is presented in Table 4 as percentages of weight of silicon-steel members compared with that of the truss as a whole. The actual weight of silicon-steel material, however, is from 80 to 90% of the amounts given, since some of the details on silicon-steel members, such as lacing, tie-plates, and rivets, are of carbon steel. Some of the percentages in Table 4 may vary, either up or down, in extreme cases by as much as 10% of their values, due to varying conditions and personal peculiarities of the computer, but generally that variation will be less than 5 per cent.

Mr. Wilbur is correct in stating that the loads per foot given in the diagrams are the totals for two trusses, rather than for one truss.

The writer's method of determining the percentage ratios for combined railway-and-highway bridges would be as follows: Let P = the percentage ratio given by the railway-bridge diagram; p = the percentage ratio for the highway-bridge diagram; W = the equivalent uniform live load, plus impact per linear foot, for the railway portion of the bridge; w = the equivalent uniform live load, plus impact, for the highway portion of the bridge; and, p' = the desired percentage ratio for the combined bridge. Then,

$$p' = \frac{W\,P + w\,p}{W + w} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

Mr. Grant's formula would be:

$$p' = P - \frac{1}{3}(P - p) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

If the railway is double-tracked (Class 60); if the clear width of the highway deck is 30 ft with Class A loading; if the structure is of carbon steel; and if the span length is taken as 400 ft,[31] W = 15 912 lb per lin ft; w = 2 475 lb per lin ft, and the curves given in the paper make $P = 25.5$ and $p = 27$. Hence, by Equation (8),

---

[31] "Bridge Engineering", by J. A. L. Waddell, M. Am. Soc. C. E., pp. 106, 129, 117, and 131.

$$p' = \frac{15\,912 \times 25.5 + 2\,475 \times 27}{15\,921 + 2\,475} = 25.7\%$$

and by Equation (9),

$$p' = 25.5 - \frac{1}{3}(25.5 - 27) = 26\%$$

The difference between Mr. Grant's percentage ratio and that of the writer is 0.3.

A similar computation for a single-track railway, a 20-ft clear roadway, and the same span length, gives 27.7% by Equation (9) and 27.3% by Equation (8), a difference of 0.4. Either difference is so small that it would scarcely show on the diagram.

Mr. Ripley's discussion reminds the writer of the days in the early Eighties when he used to consort with the "highwaymen" and compete for highway bridges. Fortunately for him, a call to Japan in 1882 took him out of that objectionable business; and upon his return to the United States four years later, he "declared war" upon all its disreputable practices and initiated what later proved to be a revolution in highway-bridge designing, letting, and construction.

The writer cannot describe in greater detail, "the loadings and other factors that affect Figs. 1 to 5", because the live loads and impacts were presented in another paper,[23] which is readily available. The percentage ratios are given in the present paper; and the manner of using them, both directly and with modifications, is fully explained. The Class A loading used is based on an 18-ton truck, and the Class B loading on a 12-ton truck.

The writer is much indebted to Mr. Allen for his trouble in computing the "percentage ratios" of the numerous bridges he has designed and built, as a check on curves of the paper. The close agreement found is a source of deep satisfaction to the writer. Of course, as Mr. Allen points out, one cannot expect perfect coincidence between the findings of any two engineers, because of the difference in their personal equations. His "percentage ratios" show a marked uniformity, indicating on the part of his computers a close adherence to specifications and the application of the principles of true economy in designing.

A further analysis of Table 2 of the paper, omitting from consideration the abnormal cases of the Springfield Bridge and the Portsmouth lift-span, indicates an average plus variation of 0.19%, an average minus variation of 0.42%, and an algebraic average of all variations equal to minus 0.25 — only one-fourth of 1 per cent. As this analysis is based upon seventeen cases, and in view of the fact that all the fifteen engineers who discussed the paper endorse the curves in general, it may be concluded that the findings of the paper are reliable; nevertheless, it would well pay any engineer who designs many bridges to plot, for the use of his office, new percentage-ratio curves based upon the specifications he utilizes and the general characteristics of his computers.

---

[23] "Economic Proportions and Weights of Modern Highway Cantilever Bridges", by J. A. L. Waddell, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 888.

The writer's experience recently has led him to construct a diagram that should prove useful, especially to beginners, in utilizing Figs. 1 and 2. The operation in so doing involves an assumption of a truss weight, checking it, assuming another and checking that, etc., until there is an exact agreement between the assumption and the check. The final weight can be found correctly from the first check weight by computing the difference between it and the assumption, and multiplying the result by the proper factor taken from the curve shown in Fig. 15. The product should be either added to or subtracted from the weight assumed, in order to determine the correct truss weight.

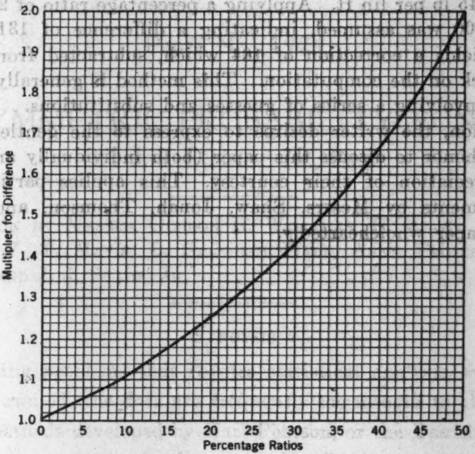

FIG. 15.—CORRECTIONS FOR ASSUMED TRUSS WEIGHTS.

As a check on the validity of this method, consider the case of a 400-ft, simple-truss bridge of 45-ft clear roadway, in silicon steel, for which Fig. 1 (*b*) gives 20 as the percentage ratio. The make-up of total vertical load (in pounds per linear foot) is as follows:

Live load plus impact	3 440
Flooring	5 470
Hand-rails	120
Floor system	1 575
Lateral system	740
Trusses (assumed)	2 600
Total vertical load	13 945

The percentage ratio of 20 gives	2 789
Assumption	2 600
Difference	189

For a percentage ratio of 20, Fig. 15 gives a multiplier of 1.25, which yields the correction: 189 × 1.25 = 236; and the correct truss weight, 2 600 + 236 = 2 836. With this truss weight, the new total vertical load will be 14 181. Applying the percentage ratio of 20, *W* = 2 836, which checks.

Had the assumption been 3 000 lb per lin ft, the total vertical load would have been 14 345 lb per lin ft. Applying a percentage ratio of 20, *W* = 2 869; a value of 3 000 was assumed, indicating a difference of 131. Multiplying 131 by 1.25 yields a correction of 164 which, subtracted from 3 000, leaves 2 836 — a check on the computation. This method is generally much quicker than the one involving a series of guesses and substitutions.

In conclusion, the writer desires to express to the gentlemen who have done him the honor to discuss this paper (both individually and collectively) his deep appreciation of their courtesy. This applies particularly to the generous comments by Messrs. Shaw, Jonah, Thomson, and Hanna, who approve the paper wholeheartedly.

AN ASYMMETRIC PROBABILITY FUNCTION

By J. J. Slade,[1] Jr., Esq.

With Discussion by Messrs. Gordon R. Williams, H. Alden Foster, R. D. Goodrich, F. T. Mavis, L. Standish Hall, Arne Fisher, Arthur W. Kempert, and J. J. Slade, Jr.

Synopsis

In engineering problems that require statistical analysis, such as studies of rainfall and run-off, the data are frequently too meager to allow the use of the elaborate methods developed by Karl Pearson, or the Danish statisticians; and yet, the asymmetries in the frequency distributions associated with these problems are usually sufficiently marked to place the investigation in a field definitely outside that of the simple Gaussian theory. Unfortunately, where the basic probability function is other than the "normal curve", the determination of the constants involved, as well as the graduation of the data, generally becomes a difficult task. Furthermore, unless the data are very complete, the final results will seldom have meaning because of the magnitude of the probable errors of the parameters involved.

The purpose of this paper is to introduce a function that differs as little as it seems possible to let it differ from the "normal" in its general characteristics, while allowing it an unlimited degree of "skewness". At the same time, it is an easy curve to apply, as such things go, and one for the application of which existing tables may be used. The paper is subdivided into the following parts:

Section I contains a critical discussion of the various methods in use at present in the analysis of frequency distributions. The purpose of this section is, first of all, to contrast and to compare the function introduced with those already in use so that both its merits and defects will be exposed at the beginning. It will thus be seen to contain a justification for the intro-

---

Note.—Published in October, 1934, *Proceedings*.

[1] Asst. Prof. of Eng. Mechanics, Rutgers Univ., New Brunswick, N. J.

duction of a new function in a field that literally teems with such studies. It is hoped that this paper will also help the engineer to a better understanding of a subject the approach to which is barricaded by so many mathematical hurdles.

The requirements of a function that is to be one degree more general than the Gaussian, are discussed in Section I. This function is introduced in Section II and is subjected to detailed mathematical analysis, and the constants of the curve are expressed in terms of the moments of the distribution which it is to fit. Finally, it is proved that the curve is a true generalization of the Gaussian, becoming identical with it, in fact, when the skewness parameter vanishes.

In Section III the formulas derived in Section II are collected and a procedure for their use is outlined. A number of examples are given which serve both to illustrate the manipulation of the new curve and to compare the results obtained by its use with those obtained by the use of other functions.

In Section IV, finally, the most general homograde function is discussed. Its parameters are expressed in terms of the bounds and standard deviation of the statistics, and a procedure for its application is outlined.

NOTATION

The following symbols used in the paper are summarized herewith for the guidance of discussers:

$\left.\begin{matrix}a\\c\\d\end{matrix}\right\}$ = parameters of the frequency function.

b = a parameter that corresponds to the maximum lower deviation of the statistics from their arithmetic mean.

g = a parameter that corresponds to the maximum upper deviation of the statistics from their arithmetic mean.

$\lambda_1, \lambda_2, \lambda_3$, etc. = parameters of the observed frequency distribution.

X = magnitude of the variate. This may be the absolute magnitude, but usually it stands for serial numbers of the classes into which the variate has been grouped.

M = arithmetic mean of the quantities, X.

x = deviations of the variate from arithmetic mean, $= X - M$.

y = frequency ordinate corresponding to the deviation, x.

Y = probability of the occurrence of deviations less than, or equal to, the deviation, x.

z = a variable abscissa; also transformed argument of probability integral.

u = a "dummy" variable of integration.

$\left.\begin{matrix}f\\F\\K\end{matrix}\right\}$ = functional symbols.

ϕ = symbol of frequency function.

ϕ_0 = symbol of generic frequency function: A first approximation to ϕ.
$\phi_1, \phi_2, \ldots$ = successive derivatives of ϕ_0.
$o_1, o_2, \ldots$ = magnitudes of observations.
$x_1, x_2, \ldots$ = distinct magnitudes of observations.
k = the last number of a finite series of parameters; also, k = a substitution factor when so identified in the text.
m = the last number of a finite series of distinct magnitudes.
n = the last number of a finite series of observations.
N = the total number of items in a statistical series = S_0.
$\left.\begin{matrix} r \\ s \end{matrix}\right\}$ = indices of summation.
λ = an index which takes on the values, 0, 1, 2, 3.
S_λ = sum of the λ powers of the deviations from the arithmetic mean = Σx^λ.
μ_λ = λth moment of the distribution = $\dfrac{S_\lambda}{S_0} = \dfrac{\Sigma x^\lambda}{N}$. Thus, $\mu_2 = \sigma^2$, the square of the standard deviation, or, if the mean is taken as the unit, $= (CV)^2$, the square of the Hazen-Foster coefficient of variation.
β = the coefficient of skewness. This is identical with $\sqrt{\beta_1}$ of the Pearson theory, and with (CS), the coefficient of skew, of the Hazen-Foster development. (In engineering literature the divisor of the moments is usually taken as $N - 1$ instead of N. This, no doubt, comes from least square usage, but in this connection the writer finds no justification for it.)
σ = the standard deviation $= \sqrt{\mu_2} = M\,(CV)$.
$\left.\begin{matrix} k \\ l \\ M_\lambda \\ v \\ w \end{matrix}\right\}$ = substitution factors.
t = a parameter connected with β by the equation, $t^3 + 3t - \beta = 0$.
$\left.\begin{matrix} A \\ B \end{matrix}\right\}$ = conjugate components of the real root of $t^3 + 3t - \beta = 0$.
ϵ = a small quantity that vanishes with t.
$O(\ )$ = "terms of the order of", a symbol denoting a small quantity which vanishes with the infinitesimal enclosed in the brackets.
e = base of Naperian logarithms.
Σ = sign of summation.

I.—Theories and Methods in Use

1.—The Normal Curve.—The most satisfactory basis for a great variety of statistical studies is the Gaussian "normal curve"[3]:

$$y = \frac{1}{\sqrt{2\pi\mu_2}}\, e^{-\frac{x^2}{2\mu_2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which, y = the frequency ordinate corresponding to the variation, x; $\mu_2 = \sigma^2$ = the second moment; e = Naperian base of logarithms; and,

---

[3] "The Mathematical Theory of Probability," by Arne Fisher, p. 198, Macmillan, 1930.

x = a variation from the arithmetical mean of the statistics. This function has been the basis of elaborate theories of errors and correlation, principally, no doubt, because its properties are mathematically simple. This is not all, however. There seems to be considerable theoretical justification for its use, although this is in no way comparable to the justification derived from experimental verification of the results obtained from its use. Under certain conditions it gives reliable information; this is a matter subject to controlled experiment. Its use is indicated whenever the following assumptions can be made regarding the variation of the entity considered[3]:

(*a*) The most probable (or most frequent) value of a large number of observations is their arithmetic mean.

(*b*) Small variations are more likely to occur than large ones.

These or equivalent assumptions relate to the variate; in addition, of course, the foundations of probability theory are assumed.

As long as the variation comes fairly well within this set the normal curve represents the data surprisingly well, and more significant than mere "fitting" of the given data is the fact that the information obtained by its use (as in extrapolating, for instance) is surprisingly accurate. The single parameter of "spread" seems adequate to take care of the possible configurations of such a set.

In engineering problems, however, these assumptions can seldom be made outside the case of direct and precise measurements. Usually the mean, the mode, and the median do not coincide.

Since the relation between negative and positive variations is not known when the symmetry that leads to the Gaussian distribution is lacking, a general frequency function cannot be developed entirely from *a priori* considerations. This leads to investigation of all the mathematical expressions that share with the probability function its characteristics properties, among which, *a fortiori,* must be the curve that is sought; and, since there is no method of generating all such curves, the investigator must finally be content to try as many of them as he can discover and to let experience be the final arbiter of the success of the search.

The extension of the theory to include skew probability functions has been the subject of much ingenious mathematical research.

2.—Pearson's Curves.—One of the first extensions of the theory, and perhaps still the most successful, is due to Karl Pearson,[4] who embodied the asymmetric assumptions regarding the frequency of the variations into the very general differential equation:

$$\frac{dy}{dx} = \frac{y(x+a)}{F(x)} \quad \text{.........................} (2)$$

which merely states that the curve has a maximum at the point, $x = -a$, and that it approaches the axis of x asymptotically as the frequency vanishes.

---

[3] For a complete proof that the normal law follows from the principle of the arithmetic mean and the theorem on compound probabilities, see "Advanced Calculus", by E. B. Wilson, Ginn & Co., 1912, p. 386.

[4] "Frequency Curves and Correlation", by W. P. Elderton, Lond., 1927.

The normal curve is obtained from the family generated by Equation (2) simply by letting $F(x)$ = a constant. It is the simplest one of all; but this mode of generation is not altogether satisfactory because, whereas Equation (2) may contain all frequency curves, it is quite likely that it also contains many curves not even remotely related to frequency functions. Equation (2) does not provide a means of distinguishing between them; for, certainly, the problem of frequency distribution is not merely one of fitting, as well as possible, a curve to a set of data; there must be some kind of theory connected with it, as strong, if possible, as that which supports the normal curve. This is a desideratum not likely to be attained, but one which must be aimed at, nevertheless, in searching for general probability functions.

Another difficulty with Pearson's set-up is a practical one. The form of the function, $F(x)$, that appears in Equation (2) must be limited severely in order to integrate the equation at all. Pearson assumed that $F(x)$ can be developed in a Maclaurin series and that it is permissible to drop all the terms of the series after the square. This is merely a roundabout and unscientific manner of assuming that $F(x)$ is a quadratic.

However, the family of curves generated by Equation (2) under the assumption that,

$$F(x) = b_0 + b_1 x + b_2 x^2 \dots\dots\dots\dots\dots\dots\dots(3)$$

has proved to be very useful. One of the principal objections to the family generated by Equation (2) is the variety of types into which it is divided. The criteria for this or that type are artificial and cumbrous. The objection is not altogether æsthetic; in order definitely to place a distribution in this or that category it is necessary to compute the fourth moment; and when the data are meager (as happens frequently in problems investigated by the engineer), a fourth moment is as meaningless as it is laborious to compute. Any accidental irregularity in the distribution is exaggerated dangerously in the higher moments. Even the third moment is quite unreliable when the observations are few. Nothing beyond the standard deviation is reliable for less than 150 items.

Of course, this family contains curves that may be specified completely by three moments (two when $\mu_1 = 0$; that is, when the origin is at the mean). One such is the curve classified as Type III; but this curve degenerates into an L-shaped figure for certain ranges of the parameters, which suffices to throw it out of the class of curves that represent possible homograde frequency distributions.

3.—The General Theory.—A general theory of frequency functions has been developed, following the researches originated by Laplace, which is extremely elegant mathematically, but quite impracticable in fact. (The best treatise, in English, on the theory of frequency curves as developed by the Danish school of statisticians, is that presented by Arne Fisher[5].) The theory is based on a fundamental property of frequency functions, namely, that if one has a set of observations, $o_1, o_2, \ . \ . \ . \ ; o_n$, and a set of numbers, $x_1, x_2, \ . \ . \ . \ , x_m$, which represent the distinct values of the observations, then, if $\phi(x)$ is the frequency function for the o's and $f(x)$ is any single-valued function at all, one may obviously write:

---

[5] "The Mathematical Theory of Probability", by Arne Fisher, Macmillan, 1930.

$$\sum_{r=1}^{r=n} f(o_r) = \sum_{r=1}^{r=m} f(x_r)\ \phi(x_r) \ldots\ldots\ldots\ldots\ldots(4)$$

Now, $\phi(x)$ is a function not only of the different values of the variate, but also of certain statistical parameters (the moments, for example, would be one such set); and, to a great extent, it is a matter of convenience what functions of the observations these parameters should be. For instance, they may be defined in this manner: Call the parameters, $\lambda_1, \lambda_2, \ . \ . \ . \ , \lambda_k$, and take two convenient functions, $F(z, \lambda_1 \ . \ . \ . \ , \lambda_k)$ and $\sum_{r=1}^{r=n} K(z, o_r)$. Now, if these two functions are equated and required to be equal for all values of z, a relation may be established in this manner between the parameters, λ_r, and the observations, o_r, because, by expanding both sides of the equation,

$$F(z, \lambda_1 \ . \ . \ . \ , \lambda_k) = \sum_{r=1}^{r=n} K(z, o_r) \ldots\ldots\ldots\ldots\ldots(5)$$

into series of powers of z and equating like powers, a relation is established between the parameters, λ_r, and the observations, o_r, that must hold for Equation (5) to be satisfied identically. By making use of Equation (4), Equation (5) may be written in this manner:

$$F(z, \lambda_1, \ . \ . \ . \ , \lambda_k) = \sum_{r=1}^{r=m} K(z, x_r)\ \phi(x_r) \ldots\ldots\ldots(6)$$

or, passing to the limit in some reasonable manner:

$$F(z, \lambda_1, \ . \ . \ . \ , \lambda_k) = \int_{-\infty}^{\infty} K(z, x)\ \phi(x)\ dx \ldots\ldots\ldots\ldots(7)$$

This is an integral equation in which, from Equation (5), both $F(z, \lambda)$ and $K(z, x)$ are known, and from which $\phi(x)$ may be determined by the rules established in the theory of such equations. The success with which efforts to solve Equation (7) will be rewarded, will depend on the ingenuity used in defining Equation (5).

Thiele obtained a solution of Equation (7) in terms of his famous semi-invariants.[*] In Thiele's solution, $\phi(x)$ is given as a definite integral which, unfortunately, cannot be integrated; so that the net result is an elegant mathematical process which ultimately gets nowhere. Even if one could make direct use of Thiele's solution of Equation (7) there are certain circumstances that render it too general for ordinary purposes. In a manner somewhat analogous to the case of Pearson's differential equation, one may say that although Equation (7) certainly includes all frequency functions, it includes no theory of actual frequency functions. A fairly arbitrary function, $\phi(x)$, may satisfy Equation (7) without being remotely near an actual frequency function.

---

[*] "The Mathematical Theory of Probability", by Arne Fisher, 1930, p. 191.

4.—The Gram-Charlier Series.—A much more practical development of the frequency function is the series named after Gram and Charlier. If one writes:

$$\phi_0(x) = \frac{1}{\sqrt{2\pi}} e^{-0.5x^2} \quad \text{.................} (8a)$$

and,

$$\phi_k(x) = \frac{d^k \phi_0(x)}{dx^k} \quad \text{.....................} (8b)$$

then the frequency function may be represented thus,

$$\phi(x) = c_0\phi_0(x) + c_1\phi_1(x) + c_2\phi_2(x) + \text{.............} (9)$$

In this series the values of c_n may be obtained by making use of the orthogonal properties of the ϕ's, or they may be obtained by the usual method of least squares.[7] W. F. Osgood has written an elementary discussion of series of orthogonal functions and their connection with the principle of least squares.[8] Here, again, the criticism is that Equation (9) is too general; it represents a statement in mathematical analysis rather than one in the theory of frequency functions. In fact, if one is satisfied with some condition slightly less than an absolute mathematical approach to a limit, Equation (9) may be used to represent, very closely, quite fantastic functions—even discontinuous ones—provided they and their slopes vanish at infinity. Clearly, this includes some functions not at all connected with frequency functions.

Furthermore, if $\phi(x)$ deviates appreciably from $\phi_0(x)$ (that is, if it has a marked skew), it may take thousands of terms of Equation (9) to get even a fair representation—and this is a process which is practically impossible. The function, $\phi(x)$, need not deviate greatly from $\phi_0(x)$ before waves and negative frequencies appear by the use of a few terms of Equation (9), and they certainly do not belong in an actual frequency curve. The reason for these spurious phenomena will be obvious to the reader acquainted with Fourier analysis.

A generating function, $\phi_0(x)$, may be defined by a relation other than Equation (8) such that, to begin with, $\phi(x)$ and $\phi_0(x)$ will be fairly similar. Then, $\phi(x)$ may be closely represented by a few terms of Equation (9). This is so because each term represents a correction to the sum of the terms that precede it. Studies have been made of various forms of the generic function, $\phi_0(x)$[9], but the objection to the use of Equation (9) must always remain: That this series, regardless of the form of the generic, $\phi_0(x)$, may be made to represent almost anything. It offers no theory of frequency functions.

---

[7] "The Mathematical Theory of Probability", by Arne Fisher, 1930, pp. 199 *et seq.*

[8] "Advanced Calculus", by William Fogg Osgood, Macmillan, 1925.

5.—Transformations of the Variate.—For greatly skewed distributions a logarithmic transformation of the variate has sometimes proved useful.[10] This transformation really furnishes a new generic function, defined, according to Fisher, by

$$\phi_0(x) = \frac{1}{n\sqrt{2\pi}} e^{-(\log \frac{x-m}{n})^2} \ldots\ldots\ldots\ldots\ldots (10)$$

to be used in Equation (9), and, therefore, it needs no further discussion than that of Article 4. The transformation has been suggested by the fact that when the skew of the frequency is great, that of the logarithms of the variate is more nearly normal. Special mention is made of this transformation because of its relation to the partly bounded function introduced in this paper. As objections to it other than those listed in Article 4 the following may be stated:

(*a*) The use of Equation (10) implies the solution of a cubic, distinct for each problem.

(*b*) After the transformation is accomplished one still has to determine the constants of the series by the method of least squares or by some equivalent process.

6.—Empirical Curves.—So-called empirical curves are not essentially different from any of the foregoing because, as a matter of fact, all the curves are empirical; but they suffer from the fact that they are usually devised for particular problems and the range of their applicability is generally quite limited. Furthermore, they are farther from an approximation of any theory of frequency functions than any of the foregoing. It is the integral, or duration, curve (for many purposes more important than the frequency function) which is often represented by means of purely arbitrary functions. Not much can be said in their favor except, perhaps, that they may be easy to use. The principal objection to their use lies in the fact that it is not possible to estimate the reliability of the parameters entering in them. The estimate of this reliability is an important phase of a statistical investigation often neglected in engineering applications.

7.—Graphical Methods.—The use of "probability" paper and other graphical devices is an undesirable practice. These methods convey to the eye a simplicity which does not really exist. The process of using these methods is not essentially different from that of fitting a curve to the data, except for the fact that one is more likely to fit the wrong curve graphically than analytically. A paper marked off in non-rectangular co-ordinates does to the data exactly what a flat map of a curved earth does to geography. One gets an exaggerated idea of the entire problem. A straight line that seems to fit the data closely may not be a good fit at all when one remembers that small deviations in certain regions of the paper may represent quite large errors. Fitting a straight line to data that plot approximately as a straight line is like using the method of least squares without weighting for functional distortion.

---

[9] See, for instance, "Generalizations of the Normal Curve of Error", by Luis R. Salvosa, Dissertation, Univ. of Michigan, Edwards Bros., Inc., Ann Arbor, Mich.

[10] "The Mathematical Theory of Probability", by Arne Fisher, 1930, pp. 236 *et seq.*

One notable exception is presented by the closely allied semi-graphical methods of Dr. J. C. Kapteyn[11] and R. D. Goodrich, M. Am. Soc. C. E.[12] Their procedures are fundamentally sound. The weakness in their methods is due to the impossibility of computing the probable errors of the constants in their functions. There is no graphical process that gives an indication of these errors.

II—The Partly-Bounded Function

1.—Desiderata.—From the discussion of Section I it is seen that only one function furnishes something of a theory of variations, and that is the normal curve, Equation (1). The succeeding developments, although no doubt including the general theory of frequency functions within their scope, are far too general in character; in spite of all that may be said against them, the Pearson functions still remain the most useful. The introduction of a new function will be justifiable only in so far as it is able to call forth a minimum of objections that must surely be raised against it. The various requirements for it will now be listed and discussed. These requirements embody the writer's theory of the most general homograde probability function:

(*a*) It must be a simple extension of the normal curve; that is, the normal curve must be one of its possible forms, and for no range of the parameters that specify it must it lose its characteristic shape. It must be smooth, without waves, and without negative frequencies. It is true that waves will be exhibited legitimately by multi-modal distributions, but these must be considered as the superposition of several uni-modal distributions.

(*b*) It should be capable of assuming indefinite skewness. Since the factors that cause skewness in the frequency of a set of variations are not known, deviations from the normal may be assumed in some way to be connected with the fact that, usually, the variate is definitely bounded, the first deviation from the normal occurring from the fact that the variate has a minimum value, but no definite maximum. In a representative curve one may require that its skewness be a simple function of its end point. The function with one end point is here termed "partly bounded," that with two end points, "totally bounded".

(*c*) The curve must be specifiable completely by moments no higher than the third. Should it have more parameters than may be so specified, then it must be possible to find some extra-statistical means of determining them. Since the probable errors in the parameters increase greatly with the order of the moments necessary to specify them, it becomes necessary to search for some physical substitutes for these moments. Two such substitutes, it will be shown, are the upper and lower bounds of the variation, when these bounds can be determined *a priori*.

---

[11] "Skew Frequency Curves in Biology and Statistics", by J. C. Kapteyn and M. J. van Uven, Hoitsema Bros., Groningen, 1916.

[12] *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 1 *et seq.*

(*d*) The curve must be simple to apply. Considering all the uncertainty that lies at the base of the theory of frequency functions, the information derived from their use is certainly not worth the expenditure of great labor in their application.

2.—The Partly Bounded Function.—Consider, first, the function:

$$y = a\, e^{-c^2 [\log d(x+b)]^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

which is defined from $x = -b$ to $x = \infty$. This function which is a first extension of the normal, admits of complete mathematical analysis. The study of it will be a guide in determining the parameters of the totally bounded function of Section IV.

Notice, in the first place, that Equation (11) is similar to the logarithmically transformed function, Equation (10), differing from it only in the power, c^2, to which it is raised. The difference is fundamental, however. It is just this added parameter, c, that makes Equation (11) more than a "normal" for the logarithms of the variate and which brings about a remarkable simplification of the formulas. It is this c, indeed, that makes Equation (11) a true generalization of Equation (1), as will be shown subsequently.

The discussion that follows immediately is a mathematical investigation of the properties of this function. By the usual method of moments[4] the parameters, a, b, c, and d, are determined in terms of the moments, μ_1, μ_2, μ_3, of the data and the total frequency, N. The investigation, which is given here for the first time, is developed with sufficient detail to enable the reader not well versed in mathematical manipulations to follow each step of the reasoning. It must be kept in mind that the analysis justifies the use of this curve only in so far as it shows that the function Equation (11) meets all the aforementioned requirements.

The reader who is willing to take for granted the accuracy of the following analysis may omit the remainder of this section and proceed to Section III, where the formulas obtained in Section II are tabulated and their application is discussed.

3.—The Parameters.—Let S_λ = the power sums of the variations; that is, let,

$$S_\lambda = \Sigma\, x^\lambda,\ (\lambda = 0, 1, 2, 3) \quad \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

so that, for instance, $S_0 = \Sigma\, x^0 = N$, the total frequency. Now, require these power sums to be equal to the corresponding moments of the function Equation (11). Thus,

$$S_\lambda = a \int_{-b}^{\infty} x^\lambda\, e^{-c^2 [\log d(x+b)]^2}\, dx \quad \ldots\ldots\ldots\ldots (13)$$

To integrate, let $z = \log d\,(x + b)$; then, $x = d^{-1} e^{z} - b$; $dx = d^{-1} e^{z}\,dz$; and,

$$x^{\lambda} = d^{-\lambda}\,[e^{\lambda z} - \lambda\, b\, d\, e^{(\lambda-1)z} + \ldots\ldots (b\,d)^{\lambda}] \ldots\ldots\ldots\ldots(14)$$

Substituting in Equation (13):

$$S_{\lambda} = \frac{a}{d^{\lambda+1}} \int_{-\infty}^{\infty} [e^{\lambda z} - \lambda\, b\, d\; e^{(\lambda-1)z} + \ldots.]\, e^{z - c^2 z^2}\, dz \;\ldots(15)$$

Equation (15) is a sum of integrals of the type, $\int_{-\infty}^{\infty} e^{kz - c^2 z^2}\,dz$.

Completing the square of the exponent in the integrand:

$$\int_{-\infty}^{\infty} e^{kz - c^2 z^2}\,dz = \int_{-\infty}^{\infty} e^{-c^2\left(z^2 - \frac{k}{c^2}z + \frac{k^2}{4c^4} - \frac{k^2}{4c^4}\right)}dz$$

$$= e^{\left(\frac{k}{2c}\right)^2} \int_{-\infty}^{\infty} e^{-c^2\left(z - \frac{k}{2c^2}\right)^2} dz = \frac{\sqrt{\pi}}{c}\, e^{\left(\frac{k}{2c}\right)^2} \;\ldots\ldots\ldots(16)$$

by a well-known result of the integral calculus.[13] Using this result in Equation (15):

$$S_{\lambda} = \frac{a}{d^{\lambda+1}} \frac{\sqrt{\pi}}{c} \left[e^{\left(\frac{\lambda+1}{2c}\right)^2} - \lambda\, b\, d\, e^{\left(\frac{\lambda}{2c}\right)^2} + \ldots.\; (b\,d)^{\lambda}\, e^{\frac{1}{4c^2}} \right] \ldots\ldots\ldots\ldots\ldots(17)$$

This gives four equations (one each for $\lambda = 0, 1, 2,$ and 3) with which to determine the constants, a, b, c, and d, in terms of the power sums, S_0, S_1, S_2, and S_3.

To solve Equation (17) let,

$$l = e^{\frac{1}{4c^2}};\quad M_{\lambda} = S_{\lambda} \frac{c\, d^{\lambda+1}}{a\sqrt{\pi}} \;\ldots\ldots\ldots\ldots(18)$$

then Equation (17) may be written:

$$M_0 = l \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(19a)$$

$$M_1 = l^4 - b\, d\, l \ldots\ldots\ldots\ldots\ldots\ldots\ldots(19b)$$

---

[13] "Advanced Calculus", by F. S. Woods, p. 153, Ginn & Co., 1926.

$$M_2 = l^9 - 2\,b\,d\,l^4 + (b\,d)^2\,l \quad\text{(19}c\text{)}$$

and,

$$M_3 = l^{16} - 3\,b\,d\,l^9 + 3\,(b\,d)^2\,l^4 - (b\,d)^3\,l \quad\text{(19}d\text{)}$$

Solving for the powers of l:

$$l = M_0 \quad\text{(20}a\text{)}$$

$$l^4 = M_1 + b\,d\,M_0 \quad\text{(20}b\text{)}$$

$$l^9 = M_2 + 2\,b\,d\,M_1 + (b\,d)^2\,M_0 \quad\text{(20}c\text{)}$$

and,

$$l^{16} = M_3 + 3\,b\,d\,M_2 + 3\,(b\,d)^2\,M_1 + (b\,d)^3\,M_0 \quad\text{(20}d\text{)}$$

Now, $\dfrac{M_\lambda}{M_0} = d^\lambda\,\mu_\lambda$, $(\lambda = 1, 2, 3)$, in which, according to the usual convention, μ_λ is the λth moment. Dividing Equations (20*b*), (20*c*), and (20*d*) by Equation (20*a*):

$$l^3 = d(\mu_1 + b) \quad\text{(21}a\text{)}$$

$$l^8 = d^2(\mu_2 + 2b\mu_1 + b^2) \quad\text{(21}b\text{)}$$

and,

$$l^{15} = d^3(\mu_3 + 3b\mu_2 + 3b^2\mu_1 + b^3) \quad\text{(21}c\text{)}$$

a set from which a has been eliminated. The usual simplification may now be introduced, which in no way affects the generality of the results, obtained by choosing the origin at the mean so that $\mu_1 = 0$. Now, let $k = \dfrac{l^2}{d}$, so that Equations (21) become:

$$kl = b \quad\text{(22}a\text{)}$$

$$k^2\,l^4 = \mu_2 + b^2 \quad\text{(22}b\text{)}$$

and,

$$k^3\,l^9 = \mu_3 + 3\,b\,\mu_2 + b^3 \quad\text{(22}c\text{)}$$

Eliminating b and the combination, kl, from Equations (22):

$$\mu_3 + 3\,\frac{\mu_2^{1.5}}{\sqrt{l^2 - 1}} = \frac{\mu_2^{1.5}}{(l^2 - 1)^{1.5}}\,(l^6 - 1)$$

that is,

$$\frac{\mu_3}{\mu_2^{1.5}} = \frac{l^6 - 1 - 3\,(l^2 - 1)}{(l^2 - 1)^{1.5}} = \sqrt{l^2 - 1}\,(l^2 + 2) \quad\text{(23)}$$

an equation in which all the parameters of the curve except c have disappeared. Let $\beta = \dfrac{\mu_3}{\mu_2^{1.5}}$ and $t = \sqrt{l^2 - 1}$. Then, Equation (23) becomes:

$$t^3 + 3\,t - \beta = 0 \quad\text{(24)}$$

a cubic with one real root equal to:

$$t = A^{\frac{1}{3}} + B^{\frac{1}{3}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

in which, $A = \frac{\beta}{2} + \sqrt{\frac{\beta^2}{4} + 1}$; and $B = \frac{\beta}{2} - \sqrt{\frac{\beta^2}{4} + 1}$.

In terms of t all the parameters of the curve have simple expressions. For $l^2 = t^2 + 1$ and from Equation (18), $\frac{1}{2\,c^2} = \log\,(t^2 + 1)$; or,

$$c = [2 \log\,(t^2 + 1)]^{-0.5} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

and,

$$b = k\,l = \frac{\sqrt{\mu_2}}{\sqrt{l^2 - 1}} = \frac{\sqrt{\mu_2}}{t} \quad \ldots\ldots\ldots\ldots\ldots\ldots (27)$$

By definition, $k = \frac{l^2}{d}$. Therefore, from Equation (27):

$$d = \frac{t}{\sqrt{\mu_2}}\,l^3 = \frac{t\,(t^2 + 1)^{1.5}}{\sqrt{\mu_2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (28)$$

and, finally, since by Equation (17), $S_0 = N = \frac{a\sqrt{\pi}}{c\,d}\,e^{\frac{1}{4c^2}}$:

$$a = \frac{S_0 c\,d}{\sqrt{\pi}}\,e^{-\frac{1}{4c^2}} = \frac{S_0 c\,d}{\sqrt{\pi}}\,e^{-\log\sqrt{t^2+1}}$$

$$= \frac{N}{\sqrt{\pi}}\,\frac{1}{\sqrt{2\log\,(t^2+1)}}\,\frac{t\,(t^2+1)^{1.5}}{\sqrt{\mu_2}}\,\frac{1}{\sqrt{t^2+1}}$$

$$= \frac{N}{\sqrt{2\,\pi\,\mu_2}}\,\frac{t\,(t^2+1)}{\sqrt{\log\,(t^2+1)}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (29)$$

4.—The Duration Curve.—The probability that the variate lies between $-\,b$ (the zero of the function) and x is expressed by:

$$Y = a \int_{-b}^{x} e^{-c^2[\log d\,(x+b)]^2}\,dx \quad \ldots\ldots\ldots (30)$$

or, making use of the transformation at the beginning of Article 3, Section II,

$$Y = \frac{a}{d} \int_{-\infty}^{\log d\,(x+b)} e^{z - c^2 z^2}\,dz$$

$$= \frac{a}{d}\,e^{\frac{1}{4c^2}} \cdot \int_{-\infty}^{\log d\,(x+b)} e^{-c^2\left(z - \frac{1}{2c^2}\right)^2}\,dz$$

Now, let $u = c\ (z - \frac{1}{2\,c^2})$, $du = c\,dz$, and the duration curve becomes:

$$Y = \frac{a}{c\,d}\,e^{\frac{1}{4c^2}} \int_{-\infty}^{c\left[\log d\,(x+b) - \frac{1}{2c^2}\right]} e^{-u^2}\,du$$

$$= \frac{N}{\sqrt{\pi}} \int_{-\infty}^{c \log \frac{d\,(x+b)}{t^2+1}} e^{-u^2}\,du \quad \ldots\ldots\ldots\ldots\ldots (31)$$

This is the ordinary probability integral with argument, $c \log \dfrac{d\,(x + b)}{t^2 + 1}$.

5.—*The Elements of the Curve.*—A few points on the curve are of special interest:

(*a*) The End Point: When $x = -b$, the curve obviously ends because there are no real values of y for $x < -b$. Since, for every real value of t there is one and only one real value of β and, conversely, it is a mere matter of convenience whether t or β is designated the coefficient of skewness. With this in mind, it is seen from Equation (27) that the skewness of the curve is a simple function of its end point, as was required of it in Article 1, Section II. In general, however, the end point of the curve does not correspond to the zero of the data. If one is quite sure of the zero, then this value may be taken for b, in terms of which, a, c, and d may be computed by Equations (26) to (29). When this is done the third moments of the curve and data do not quite agree, but it must be remembered that the probable error in the third moment is large when the distribution is not normal, and, therefore, agreement in the third and higher moments is not a good criterion of fit.

(*b*) The Mode: To obtain the mode,

$$\frac{dy}{dx} = -2\,a\,c^2\ \frac{\log d\,(x+b)}{x+b}\ e^{-c^2\,[\log d\,(x+b)]^2} = 0 \quad \ldots (32)$$

For finite values of $x > -b$ this expression vanishes when the logarithmic factor vanishes; that is, when $d\ (x + b) = 1$. So that the mode is at:

$$x = \frac{1}{d} - b = b\left[\frac{1 - (t^2 + 1)^{1.5}}{(t^2 + 1)^{1.5}}\right] \ldots\ldots\ldots\ldots (33)$$

(*c*) The Median: To obtain the median, notice that,

$$\int_{-\infty}^{0} e^{-u^2}\,du = \int_{0}^{\infty} e^{-u^2}\,du$$

so that,

$$u = c \log \frac{d\,(x + b)}{t^2 + 1} = 0$$

or,

$$d\,(x + b) = t^2 + 1 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34)$$

and,

$$x = \frac{\sqrt{\mu_2}}{t\sqrt{t^2 + 1}} - \frac{\sqrt{\mu_2}}{t} = b\left[\frac{1 - \sqrt{t^2+1}}{\sqrt{t^2+1}}\right] \quad \ldots\ldots\ldots (35)$$

Dividing Equation (35) by Equation (33):

$$\frac{\text{Median}}{\text{Mode}} = \frac{1 - (t^2 + 1)^{0.5}}{1 - (t^2 + 1)^{1.5}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (36)$$

which, for all values of *t*, is less than 1. From Equation (36) it is seen that the median always lies between the mode and the mean.

6.—The Normal Curve as a Limiting Form.—The next step is to inquire what shape this curve will have as *t* approaches 0; that is, as the skewness vanishes:

$$\underset{t \longrightarrow 0}{\text{limit}}\; a = \underset{t \longrightarrow 0}{\text{limit}}\; \frac{N}{\sqrt{2\,\pi\,\mu_2}}\;\frac{t\,(t^2+1)}{\sqrt{\log\,(t^2+1)}}$$

$$= \underset{\longrightarrow 0}{\text{limit}}\; \frac{N}{\sqrt{2\,\pi\,\mu_2}}\;\frac{t\,(t^2+1)}{\sqrt{1 - \dfrac{t^2}{2} + \dfrac{t^4}{3} - \ldots}} = \frac{N}{\sqrt{2\,\pi\,\mu_2}} \quad \ldots\ldots (37)$$

and,

$$\underset{t \longrightarrow 0}{\text{limit}}\; c\,d = \underset{t \longrightarrow 0}{\text{limit}}\; \frac{t\,(t^2+1)^{1.5}}{\sqrt{\mu_2}\,\sqrt{2\log\,(t^2+1)}}$$

$$= \underset{t \longrightarrow 0}{\text{limit}}\; \frac{t\,(t^2+1)^{1.5}}{\sqrt{2\,\mu_2}\; t\,\sqrt{1 - \dfrac{t^2}{2} + \ldots}} = \frac{1}{\sqrt{2\,\mu_2}} \quad \ldots\ldots\ldots (38)$$

so that, for small values of *t*, $cd = \dfrac{1}{\sqrt{2\,\mu_2}} + \epsilon$; and,

$$d = \frac{1}{c}\left(\frac{1}{\sqrt{2\,\mu_2}} + \epsilon\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (39)$$

in which, ϵ is a small quantity that vanishes with *t*.

Now, $b\,d = (t^2 + 1)^{1.5} = 1 + \dfrac{3}{2}\,t^2 + \ldots$ by the binomial theorem; or,

$$b\,d = 1 + 0\,(t^2) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (40)$$

in which, $0\,(t^2)$ is a small quantity that vanishes with t^2. Then:

$$\left.\begin{aligned} \underset{t\to 0}{\text{limit}}\ c\log d(x+b) &= \underset{t\to 0}{\text{limit}}\ \log\,[d(x+b)]^c \\ &= \underset{c\to\infty}{\text{limit}}\ \log\left[\frac{x}{c}\left(\frac{1}{\sqrt{2\mu_2}}+\epsilon\right)+1+0(t^2)\right]^c \\ &= \log e^{\frac{x}{\sqrt{2\mu_2}}} = \frac{x}{\sqrt{2\mu_2}} \end{aligned}\right\} \quad \ldots\ldots (41)$$

The existence of this limit (Equation (41)) may be shown by applying the rule of L'Hospital.[14] Combining these various results:

$$\underset{\beta\to 0}{\text{limit}}\ a\,e^{-c^2\,[\log d\,(x+b)]^2} = \frac{1}{\sqrt{2\pi\mu_2}}\,e^{-\frac{x^2}{2\mu_2}} \quad \ldots\ldots (42)$$

III.—The Use of the Function

1.—The Computation of the Parameters.—To fit the curve to a set of data compute the moments, μ_2 and μ_3, in the usual way; then compute $\beta = \frac{\mu_3}{\mu_2^{1.5}}$, followed by A, B, and t (Equation (25)). It will be found convenient to compute immediately the quantities, t^2+1; $t\,(t^2+1)$; $\sqrt{t^2+1}$; and $\sqrt{2.303\ .\ .\ .\ \log_{10}(t^2+1)}$. (The logarithms of the last section are to the base, e. Consequently, $\log x = 2.303\ .\ .\ .\ \log_{10} x$.)

In terms of these quantities the parameters are:

$$\sqrt{2\pi}\,a = \frac{N}{\sqrt{\mu_2}}\ \frac{t\,(t^2+1)}{\sqrt{2.303\log_{10}(t^2+1)}}$$

$$b = \frac{\sqrt{\mu_2}}{t}$$

$$\sqrt{2}\,c = \frac{1}{\sqrt{2.303\log_{10}(t^2+1)}}$$

and,

$$d = \frac{1}{\sqrt{\mu_2}}\,t\,(t^2+1)\sqrt{t^2+1}$$

Since Equation (8*a*) is the most usual form in which the normal curve is tabulated, the quantities, $\sqrt{2\pi}\,a$ and $\sqrt{2}\,c$, are computed instead of a and c.

Table 1 gives the values of these parameters for selected values of β for $\sigma = 1$. If σ is not 1, this table may be used with $\frac{x}{\sigma}$ and $\frac{a}{\sigma}$.

---

[14] "Advanced Calculus", by F. S. Woods, p. 18.

Table 2 has been constructed to give deviations from the mean for selected frequencies (given herein as percentages of time), and is similar to tables[15] constructed by H. Alden Foster, M. Am. Soc. C. E., for Pearson's Type III curve. Only extreme values are given, as this curve plots fairly straight on logarithmic probability paper. In using such a table, however, it must be remembered that appearance, particularly of a graph plotted on logarithmic probability paper, is no test of the goodness of fit.[16]

A point that will be found useful in plotting the curve is the mode, $x = \dfrac{1}{d} - b$. If there is sufficient skewness, the end point, $x = -b$, will also help.

2.—Examples.—

Example *a.*—A problem worked out in full detail will illustrate the application of these formulas. The first problem analyzed is that given by

---

[15] "Theoretical Frequency Curves and Their Application to Engineering Problems", by H. Alden Foster, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 142.

[16] "Probability and Its Engineering Uses", by Thornton C. Fry, Chapter IX, N. Y., D. Van Nostrand Co., 1928.

Elderton,[17] which is based upon a set of data to which he fits a transition Type III curve. This particular problem was chosen because it is one in which Pearson's curve breaks up into an L-shape. Furthermore, Pearson's Type III curve may be compared fairly with the writer's in that both are specified by the same parameters. The data are listed in Table 3.

TABLE 3.—DATA UPON WHICH EXAMPLE *a* IS BASED ($N = 251$).

x (1)	Observed frequency (2)	Frequency from Pearson's Type III curve (3)	Mid-ordinates of writer's curve (4)
0.400	...	...	0
1	44	59	62
1.575	...	...	125
2	134	111	109
3	45	45	49
4	12	20	19
5	8	9	8
6	3	4	3
7	1	2	2
8	3	1	1

Although the frequencies of Column (3), Table 3, are quite close to the observed frequencies, the mid-ordinates of Pearson's curve show it to be a poor representative of this distribution, as may be seen by referring to the illustration in Elderton's book.[17] Elderton gives the elements: The mean at $x = 2.335$; $\mu_2 = 1.442$ ($\sqrt{\mu_2} = 1.201$; $\mu_2^{1.5} = 1.730$); and, $\mu_3 = 3.607$.

Consequently, $\beta = \dfrac{3.607}{1.730} = 2.085$ and, by Equation (25):

$$A = 1.042 + \sqrt{2.022} = 1.042 + 1.421 = 2.463$$

$$B = 1.042 - 1.421 = -0.379$$

and,

$$t = 1.345 - 0.724 = 0.621$$

Of course, this value of t could have been obtained closely enough from Table 1.

Next, compute the quantities: $t^2 + 1 = 1.345$; $t\ (t^2 + 1) = 0.861$; $\sqrt{t^2 + 1} = 1.178$; and, $\sqrt{2.303\ .\ .\ .\ \log\ (t^2 + 1)} = 0.574$. With these values, the parameters of the curve may be computed, as follows:

$$\sqrt{2\pi}\ a = \frac{251 \times 0.861}{1.201 \times 0.574} = 313$$

$$b = \frac{1.201}{0.621} = 1.934$$

$$\sqrt{2}\ c = \frac{1}{0.574} = 1.741$$

---

[17] "Frequency Curves and Correlation", by W. P. Elderton, p. 90, 1927.

and,

$$d = \frac{0.861 \times 1.178}{1.201} = 0.844$$

The ordinates of the curve are computed by constructing Table 4, each column being constructed from preceding columns. The values in Column (6) are from tables of Equation (8a) compiled by Messrs. F. C. Mills and D. H. Davenport.[18] The mode is at $x = \frac{1}{d} - b = -0.75$; $X = 2.335 - 0.75 = 1.575$; and, $y = 313 \times 0.3989 = 125$. The end point is at $x = -1.934$; and $X = 2.335 - 1.934 = 0.4$.

TABLE 4.—COMPUTATION TABLE FOR DETERMINING ORDINATES OF FREQUENCY CURVE

$x = X - M$ (1)	$x + b$ (2)	$d(x + b)$ (3)	log (Column (3)) (4)	$2.303 \times \sqrt{2} \times c$(Column (4)) (5)	ϕ_0 (Column (5)) (6)	$\sqrt{2\pi}\, a \times$ (Column (6)) (7)
−1.335	0.6	0.506	−0.296	−1.188	0.199	62
−0.335	1.6	1.350	0.130	0.522	0.348	109

5.665	7.6	6.410	0.807	3.240	0.002	0.6
6.665	8.6	7.252	0.860	3.450	0.001	0.3

Example b.—The next problem is one given by Fisher,[19] who makes the statement that the statistical assistants working on the problem were unable to fit the data by means of Pearson's curves.

Fisher uses the logarithmically transformed function, (Equation (10)), as a generic function. After calculating the values of m and n for this particular problem, he then determines the constants, c_0, c_3, and c_4, by the method of least squares. Unfortunately, he does not give his computed ordinates; nor does he give the ordinates for the distribution,[20] so that his curve and that of the writer for this problem can be compared only by sight from slightly different perspectives. However, a glance at Fisher's diagram[20] and at Fig. 1 of this paper is sufficient to show that the latter is at least as good a fit. Furthermore, the work required to fit these data by the present method is quite negligible compared to that which Fisher must do to obtain a result that is "satisfactory for all practical purposes".

The observed data and the ordinates computed by the present method are given in Table 5. The elements of this distribution are the following: The mean is at $x = 5.830$, with $\mu_2 = 7.245$ ($\sqrt{\mu_2} = 2.695$; $\mu_2^{1.5} = 19.502$);

---

[21] "Duration Curves", by H. Alden Foster, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 99 (1934) p. 1213.

Column (7), Table 7, gives 2.303 $\sqrt{2}\, c \log \dfrac{d\,(x + b)}{t^2 + 1}$ for the corresponding values of x. To obtain the values in Column (8) it is necessary to select the values of the probability integral (as given by Mills and Davenport,[14] for instance) corresponding to the values in Column (7). Then, 0.5 + (Column (7)) = (Column (8)), because the tables are calculated so as to give the area from 0 up to the ordinate, x.

IV.—THE MOST GENERAL FREQUENCY FUNCTION

1.—The Range of Variation.—As has been pointed out in Section III, instead of computing the third moment of the distribution, one may determine, somehow, the lower limit of the variation; then, through the relation, $b = \dfrac{\sigma}{t}$, the constants of the curve can be computed. The two processes will not lead, in general, to precisely the same result, but the discrepancy should come well within the margin of probable errors, if the present theory is correct.

It is not always easy to determine this lower point, however. In considering the heights of a group of men, for instance, one would not be justified in taking zero as the lower limit of the variation; 1 ft or 2 ft would be closer to the actual limit. Even if one were to take 0 as this lower limit, however, one would be doing something more rational than taking $-\infty$, as is always done when the normal curve is used in connection with such statistics. In fact, even in the most symmetrical cases ordinarily considered, the normal curve gives the poorest estimate of the range of the variation.

Unlimited variations do occur: There is a finite chance that a run of n heads will occur in tossing a coin no matter how large n may be; but in physical fluctuations these chances do not usually occur because the phenomenon in question does not exist in these extreme aspects.

Consequently, the problem at hand is to determine the range of variation of a statistical series under consideration. For this determination there are two alternatives: The range may be determined statistically (which is, in effect, Pearson's procedure), or, it may be determined from purely physical considerations. The statistical determination is a purely formal process which leads close to the true answer only when the data are abundant, but quite a fair estimate may be made from non-statistical considerations of the range of fluctuation of a great many physical phenomena. For instance, a stream, will certainly not run less than dry, and the greatest possible flood that can occur on it is certainly some function of its drainage area, geographical and geological location, etc.

In what follows it will be assumed that this estimate may be made. Let b = the maximum lower fluctuation from the mean of the statistics, and g = the maximum upper fluctuation.

2.—The Totally Bounded Function.—The construction of a function with both lower and upper limits is a simple generalization of the function already discussed; but the analysis of it is not straightforward. The preceding analysis, however, places one in a position to determine the parameters of the totally bounded function in terms of its end points. Since it is no longer a question of determining these parameters by the method of moments (however desirable such a determination may be), the integral curve will be dealt with directly.

The probability integral will be taken in the form in which it is most usually tabulated, namely,

$$Y = \frac{N}{\sqrt{\pi}} \int_{-\infty}^{z} e^{-\frac{u^2}{2}} du \quad \ldots\ldots\ldots\ldots\ldots\ldots (43)$$

For the partly bounded function, by substituting $\frac{\sigma}{b}$ for t in the preceding formulas:

$$z = c \log d\ (x + b) \ldots\ldots\ldots\ldots\ldots\ldots (44a)$$

in which,

$$d = \frac{\sigma}{b^2} \sqrt{b^2 + \sigma^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (44b)$$

and,

$$\frac{1}{c} = \sqrt{\log \frac{\sigma^2}{b^2} (b^2 + \sigma^2)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (44c)$$

From Equations (43) and (44), by an obvious extension, the following set of formulas is obtained for the totally bounded curve:

$$z = pc \log d \left(\frac{x + b}{g - x}\right) \ldots\ldots\ldots\ldots\ldots\ldots (45a)$$

in which,

$$d = \frac{g^2}{b^2} \sqrt{\frac{\sigma^2 + b^2}{\sigma^2 + g^2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (45b)$$

$$\frac{1}{c} = \sqrt{\log \frac{g^2}{b^2} \left(\frac{\sigma^2 + b^2}{\sigma^2 + g^2}\right)} \ldots\ldots\ldots\ldots\ldots\ldots (45c)$$

and,

$$p = \sqrt{\frac{g - b}{g + b + 2\sigma}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (45d)$$

The factor, p, has been introduced to make the second moment of the curve agree with that of the statistics. The determination has been empirical and, consequently, this factor may be found to require further modification. The considerations that have guided the writer in the present determination are the following: p must approach 1 as g approaches ∞ , and -1 as b approaches ∞. Furthermore, the product, pc, must remain finite and determinate as g approaches b.

With these elements the curve represents the most general homograde probability function, according to the present theory. It begins at a distance, b, below the mean and ends at a distance, g, above it, these points coinciding with the absolute limits of the statistics, and its mean and standard deviation coincides with those of the observed distribution. By inspection, it is seen that the partly bounded function discussed in Sections II and III is obtained by permitting either g or b recede to ∞ , the other remaining finite (in one case, the curve is right-skewed; in the other, left-skewed).

The form of this function must now be determined as g becomes equal to b; that is, as the curve becomes symmetrical, but bounded. When $g = b$, obviously $d = 1$. Assume that g is nearly equal to b so that $g^2 - b^2$ is small; then,

$$\log \frac{g^2}{b^2}\left(\frac{\sigma^2 + b^2}{\sigma^2 + g^2}\right) = \log\left[1 + \frac{\sigma^2}{b^2}\left(\frac{g^2 - b^2}{g^2 + \sigma^2}\right)\right]$$

$$= \frac{\sigma^2}{b^2}\left(\frac{g^2 - b^2}{g^2 + \sigma^2}\right) + O\left([g^2 - b^2]^2\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (46)$$

Consequently,

$$p\,c = \sqrt{\frac{g - b}{g + b + 2\,\sigma}\,\frac{\sigma^2}{b^2}\,\frac{g^2 + \sigma^2}{g^2 - b^2}} + O\,(g^2 - b^2) \quad \ldots\ \ldots\ldots (47)$$

and,

$$\lim_{g \to b} p\,c = \frac{b}{2\,\sigma}\sqrt{\frac{b^2 + \sigma^2}{b^2 + \sigma\,b}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (48)$$

Therefore, for symmetrical, bounded fluctuations the argument becomes,

$$z = \frac{b}{2\,\sigma}\sqrt{\frac{b^2 + \sigma^2}{b^2 + \sigma\,b}}\,\log\left(\frac{x + b}{b - x}\right) \quad \ldots\ldots\ldots\ldots\ldots (49)$$

from which the normal curve is obtained by letting b recede to ∞ , when one obtains, simply,

$$z = \frac{x}{\sigma} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (50)$$

It would be highly desirable to determine the parameters of this general function in terms of the moments (for this, a fourth moment would be

TABLE 8.—THE PROBABILITY INTEGRAL

Probability Y, in %-of-time	Parameter, z	Probability Y, in %-of-time	Parameter, z	Probability Y, in %-of-time	Parameter, z

				95	−1.64

required since the condition of termination at the upper end has been added) because, whether or not the present theory is tenable, this function represents the most flexible and stable curve of any in use at present. The writer, however, has found unsurmountable mathematical difficulties on the road to this goal. Table 8 is a short solution of the probability integral.

Example *d*.—To illustrate the use of the most general function given by Equations (45) the distribution of the flow peaks of the Tennessee River, at Chattanooga Tenn., will be considered. In the 57-yr daily flow record of the Chattanooga Station there are 2 440 peaks, ranging from a minimum of 3 360 cu ft per sec, to a maximum of 361 000 cu ft per sec. Their arithmetic average was found to be 49 550 cu ft per sec.

These peaks were grouped into classes of intervals of 5 000 cu ft per sec, so that $X = 1$ is the mid-ordinate (in class units) of the 0—5 000 class, or 2 500; $X = 2$ is the mid-ordinate of the 5 000—10 000 class, or 7 500; etc. The zero flow is at $X = 0.5$, and the mean is $M = 10.41$. The limits, b and g, were taken as 10 and 120 class units, respectively. This makes the range of fluctuation approximately from 0 to 650 000 cu ft per sec. No justification is offered for the selection of these limits. They are used merely for illustration. The standard deviation was computed to be 9.459 class units.

Substitution in Equations (45*b*), (45*c*), and (45*d*), gives $d = 16.47$, $c = 1.257$, and $p = 0.86$. In Table 9 three ordinates are solved to illustrate

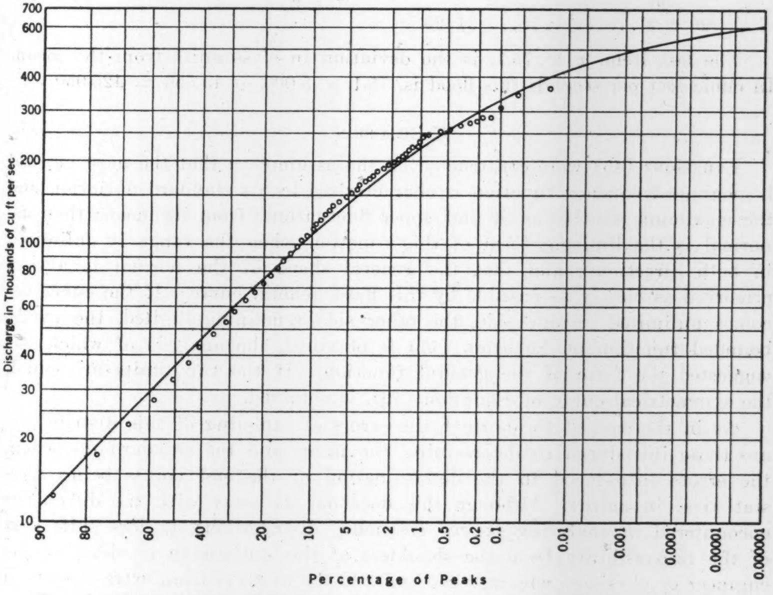

FIG. 3.—FLOW PEAKS, TENNESSEE RIVER AT CHATTANOOGA, TENN., 1875–1931.

the computation. Fig. 3 shows the observed cumulative frequencies[21] compared with the theoretical curve plotted on extreme value logarithmic probability paper.

TABLE 9.—COMPUTATION OF PROBABILITY

X (1)	$x = X - M$ (2)	$x + b$ (3)	$g - x$ (4)	$\frac{x+b}{g-x}$ (5)	$\frac{d\,(x+b)}{(g-x)}$ (6)	log Column (6) (7)	pc × Column (7) (8)	ϕ_0 (9)	Probability Y, in %-of-time (10)
5....	−5.410	4.59	125.41	0.0366	0.6027	−0.506	−0.548	0.29116	70.88
10....	−0.41	9.59	120.41	0.0796	1.3107	+0.2708	+0.293	0.61409	38.59
90....	79.59	89.59	40.41	2.2170	36.5060	3.597	3.89	0.99995	0.005

Column (9), Table 9, was obtained from the tables of Mills and Davenport.[18] If only a few values on the curve are required, Table 8 may be used as follows: Suppose it is required to find the flood likely to occur 0.01% of the time (assuming the floods equally spaced in time). Opposite 0.01 in Table 8, the value, 3.72, of z is found. The corresponding value of x may now be found by Equation (45a), arranging the computation as follows:

Y..................	0.01	$gw - bd$..........	3 585.3
z..................	3.72	$w + d$............	47.72
$v = \frac{z}{pc}$.............	3.442	$\frac{gw - bd}{w + d} = x$......	75.1
$w = e^v$.............	31.25		

The last item, $x = 75.1$, is the deviation in class units from the mean. In cubic feet per seconds this flood is, 75.1 × 5 000 + 49 550 = 425 050.

CONCLUSION

Equations (45) were constructed on the assumption that the most general homograde frequency function is characterized by its standard deviation and the maximum possible lower and upper fluctuations from its mean; that the normal is the limiting form of this function when the range is unlimited in both directions; and that the general shape of the normal is always preserved as closely as possible by this most general curve. If the curve becomes unlimited on one side, the other side remaining limited, the partly bounded function of Equation (11) is obtained, the analysis of which has suggested the form of the general function. If the two limits are equal, the symmetrical curve of Equation (49), is obtained.

As in the case of the normal, the errors of sampling of this distribution are those introduced in determining the mean and the standard deviation, the errors introduced in the determination of the end points being nonstatistical in nature. Although this does not do away with the difficulties encountered in analyzing skewed frequency distributions, it does shift part of the responsibility from the shoulders of the statistician to those of the engineer or physicist, who may set limits to the problem from extra-statistical considerations.

ACKNOWLEDGMENT

For valuable criticism and suggestions, as well as for having introduced him to a fertile and wide field of analysis, the writer wishes to take this opportunity of expressing his indebtedness to Thorndike Saville, M. Am. Soc. C. E.

While employed as Associate Statistical Engineer by the United States Geological Survey on the work of the Mississippi Valley Committee, the writer has had an opportunity to develop the totally bounded function described in this paper.

DISCUSSION

Gordon R. Williams,[22] **Jun. Am. Soc. C. E.** (by letter).—The purpose of this discussion is to compare the author's "totally bounded function" with the graphical method in the study of flow peaks. To the mathematician the graphical method is inexcusably crude, but the engineer finds in its use certain practical features that may overshadow what the mathematician considers its undesirable attributes from his standpoint of pure science. It is not proposed to delve into theory herein except to state that it is questionable whether a probability function should be applied to a study of natural phenomena which may result from the combination by summation, multiplication, and cyclical variation of various causes and conditions in a more or less indeterminate and discontinuous sequence.

Any purely mathematical treatment of stream-flow data presumes at the outset that all the data are equally reliable. Unfortunately, this is not the case. Early records are usually less reliable than present-day records, and the accurate determination of extremely high flows is more difficult than that of lower flows. These are facts familiar to the experienced hydrographer. The probable range of variation from the true discharge cannot be computed by any statistical means. If a graphical method is used to interpret these data, the curve can be shifted to give more or less weight to certain points, depending on their accuracy.

To use the author's method it is necessary to list all the flow peaks down to the lowest on record. Of course, it is a minor consideration that this is a laborious task, but it is important to consider what significance these small peaks have. There are few rivers in the United States to-day in which the low flows are not influenced by some works of Man, and, consequently, these flows would be so modified, at least in magnitude, as to have no relation to the frequency and magnitude of the higher flows. There may also be certain peculiarities of the natural drainage area and river valley which would make it doubtful whether one relation would suffice for the full range of flows. Most graphical methods do not attempt to utilize flows below the so-called "one-year flood"; that is, the smallest of the annual maximum floods.

After all the flows have been listed, it is necessary to assign an upper limit, which the author states must be determined by some extra-statistical means. The determination of this upper limit is a matter which is receiving careful consideration from many leading hydraulic engineers to-day. If it is possible to determine this limit accurately, the graphical method as well as the statistical method will benefit. For the graphical method, the upper limit will furnish an asymptote that will greatly increase the accuracy of this method, in the range between the observed data and the limit.

From studies of relatively long records it appears that any method that utilizes a record of less than 30 or 40 years will have to be adjusted for long climatic cycles. For example, any study that utilized the records of the period, 1914 to 1934, would lead in many places to a large under-estimate of the flood potentialities of the region. Phenomena that are influenced by such climatic cycles cannot be studied by mathematical means alone.

[22] Asst. Hydr. Engr., Water Resources Branch, U. S. Geological Survey, Washington, D. C.

All the methods for analyzing flood and run-off phenomena have weaknesses, but a solution of the problem will be obtained only through a combined consideration of the valuable features of each method.

H. ALDEN FOSTER,[23] M. AM. SOC. C. E. (by letter).—An excellent discussion of probability curves in general, and of the relative merits of the several types of curves which have been proposed, is contained in this paper. The author's criticisms of the Pearson curves are worthy of note, and should be helpful to any engineer who has occasion to use these curves in practical work. His comments on empirical curves and graphical methods are also significant.

Professor Slade presents a new formula for statistical analysis, and develops it mathematically, with numerical examples. This formula is proposed as a substitute for other curves (particularly those of Pearson) which have been in use for many years. He specifies several desiderata which any probability function should satisfy in order to be mathematically consistent and suitable for practical use. The proposed formula is shown to satisfy these requirements; but whether it is superior in these respects to the Pearson curves has not been clearly demonstrated. In the writer's opinion, all these desiderata are satisfied by Pearson's Type I and Type III curves, as well as can be desired for any practical engineering uses.

Requirement (*d*), that "the curve must be simple to apply", does not seem to be well substantiated from a practical standpoint. Doubtless, the proposed curve is easier to handle than some other types of probability functions; but it appears doubtful whether the average engineer would be able to make ready use of it, due to the mathematical operations involved.

As has been shown by the writer,[24] the practical application of the Pearson curves (Types I and III) can be made very simple due to the fact that, with these curves, the distance from the mean to any point on the duration curve is directly proportional to the coefficient of variation. This relation does not appear to hold for the author's formula—at least, he does not mention it. It was by virtue of this relation that the writer was able to prepare tables from which the Pearson curves could be plotted directly, as soon as the proper values of the coefficient of variation (CV) and coefficient of skew (CS) were determined.

The author has given (see Table 2) what appears to be a similar table for his curve, showing variations from the mean at several percentages-of-time, for different values of the coefficient of skew. This table is computed for a coefficient of variation, CV, equal to unity; but there is nothing to show that it can be used for any other value of CV.

---

[23] Res. Engr., Parsons, Klapp, Brinckerhoff & Douglas, North Platte, Nebr.

[24] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 158.

Examination of Table 2 indicates that the author's "partly-bounded function" gives results very close to the Pearson Type III curve for percentages-of-time greater than 0.1%; but for more extreme values of the probability scale the proposed formula gives increasingly larger values of the variation than by the Pearson curve.

To apply the new formula to a practical engineering problem, as shown in the examples given by the author, requires the computation of several constants in addition to the coefficients of variation and skew. Computation of ordinates of the frequency curve can then be made directly, by means of Equation (11); but the solution of the duration curve requires the use of a table of the probability integral which, although in common use by statisticians, is not always available to the practicing engineer. The proper method of using the table, even if available, might easily lead the average engineer into difficulties.

The foregoing comments apply particularly to the "partly-bounded function" proposed by the author. The "totally-bounded function" appears to involve still greater difficulties from a practical standpoint.

The writer has attempted to examine this paper from the viewpoint of the practical engineer. In many respects, the paper reflects the attitude of the expert mathematician or statistician rather than that of the engineer. It is quite possible that the author's formula may have great potential value in general statistical analysis. The writer does not consider himself qualified to discuss it from that angle.

R. D. GOODRICH,[25] M. AM. SOC. C. E. (by letter).—A notable contribution to the knowledge and literature of asymmetric probability functions is contained in this paper. Little need be added to the discussion, in Section I, of the general probability functions and of the curves in use at the present time. The author has emphasized clearly the practical difficulties and limitations to the use of Pearson's, Thiele's, and the Gram-Charlier series for many engineering problems. They are all mathematically "elegant"; but mathematical elegance has less appeal to the engineer than practicability.

It is well to call attention, as the author has, to the desirability of estimating the reliability of the parameters used in any method. Perhaps still more important, however, is some knowledge of the reliability of the results to be obtained from the final curve or equation. That this seldom is possible with purely empirical methods is quite true.

The writer disagrees with the author's statement to the effect that "the use of * * * and other graphical devices is an undesirable practice." On the contrary, graphical methods are frequently most desirable for the presentation and analysis of engineering and numerous other data. No doubt the author's point is that the value of graphical methods is largely lost if their limitations are not kept clearly in mind. His criticism of the writer's semi-graphical method[12] for the analysis of skew frequency distributions can be met, at least to a large extent, by adapting the method of least squares to the determination of the parameters of the function. These calculations make it possible, with little computation, to determine the probable errors of the parameters and also that of any value of the variable as read from the curve for a given percentage of time.

---

[25] Prof., Civ. Eng., and Dean, Coll. of Eng., Univ. of Wyoming, Laramie, Wyo.

An interesting graphical method for the application of least squares to the fitting of curves to data has been written by Professor E. O. Waters.[26] The writer now makes frequent use of an analytical method for Case I of Professor Water's paper, to fit the curves of his method[12] to flood data, with satisfactory results.

Professor Slade has given an excellent statement of the character desirable for an asymmetric probability function, and has presented a form for this function which meets his specifications to a remarkable degree. The solution of the equation involving this function, when partly bounded, in terms of the power sums, or moments of the data, needs no discussion.

One great advantage of the proposed function is the fact that it includes the normal curve; but a disadvantage is that this curve is a limit as to the skewness in one direction, the skewness always being toward the finite limit of the curve. This is evident from a comparison of Equations (32) and (33) and also from Equation (36), and is stated by the author in the text following Equations (45). An example of flood data for which the mode is greater than the mean, and for which there is no apparent upper limit, is that of the Mackenzie River, in Australia.[27] In this distribution the range of observations above the mean is only 85% of the range below it, although the number of observations above and below the mean is practically the same.

[26] "Graphical Methods for Least Square Problems," *Proceedings*, Applied Mechanics Div., A. S. M. E., 1928.

[27] *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 20.

The use of the new equation as an expression of the mathematical frequencies of a skew distribution, as illustrated by the computations for the data of Table 3, involves the computation of ten auxiliary quantities before the four constants of the equation can be determined. Using skew frequency paper, the writer can plot a curve[12] agreeing more closely with the data, comparatively, with little computation. All that is necessary to plot the diagram is to prepare the first four columns of Table 10.

Values of X from Column (1), Table 10, are then plotted against the cumulative values of skew frequency in Column (4) on standard, skew frequency paper, and an average, straight line is drawn by eye through the plotted points. Average values of total frequency are then read from the straight-line curve and entered in Column (5), Table 10. The determination of the data in the remaining columns is obvious. The sum of the differences between the observed and computed frequencies by the graphical method is only three-fifths as great as that resulting from the use of the analytical methods propounded by either Professor Slade or Professor Pearson, while the time and labor required for the graphical solution is only a fraction of that necessary for any analytical solution. Furthermore, the equation of the integral frequency curve requires the determination of only two constants from the diagram, the slope and intercept, which, with the total number of observations, give an equation of the form:

$$t = n\, e^{i} \qquad \text{(51)}$$

in which, $i = -\, k\, x^{-c}$. If the writer's equation involving the lower limit of the frequency curve, $-b$ in the author's notation, is used, and the values of the index and modulus are determined by least squares, very much closer agreement can be obtained between the observed and computed frequencies. Furthermore, the probable errors of these parameters can be determined also. Contrary to the author's statement, the computations for the necessary factors can be made graphically by Professor Water's method, as previously mentioned, although the writer prefers analytical methods for this work. The computation of two means and three other quantities similar to the author's moments, are all the factors necessary for the determination of the two parameters of Equation (51). The computations, therefore, are only about one-half those required by the author's method. The maximum deviation below the mean is not determined statistically by the writer's method. Theoretically, at least, Professor Slade's method has an advantage in this one respect, in that, for the partly bounded function, this quantity can be determined statistically.

It can be demonstrated that the writer's equation can be fitted to a set of observations much closer than by the use of either the author's or Pearson's functions. Furthermore, an equation with four constants, including the number of observations, n, and the lower limit, b, can be fitted without the use of products or moments of the third degree which are required in the author's solution. The use of third or higher moments is a disadvantage, especially for the shorter series of observations, on account of the increase in the magnitude of the errors in the resulting power sums for these higher moments.

This fact is recognized and mentioned by the author. The suitability of the value selected for the lower limit of the curve may be tested by use of the coefficient of correlation.

While the duration curve in Fig. 2 approximates the data fairly well, the curve crosses the evident trend of the data in the central part of the diagram instead of following it. With the writer's method[12] a curve can be fitted which has sharper curvature at each end so that the data are more closely approximated by the curve. The question, therefore, arises as to whether or not the new function is sufficiently flexible to become generally useful. The question is one that can only be answered after a great many trials with a great variety of distributions. The rainfall data used show unmistakable evidence of a disturbing influence so that the series is not especially well adapted to illustrate the use of the proposed function. Study of physical conditions might disclose two distinct distributions of storms due to separate sets of causes, which are superposed to form the records given.

The most general function proposed is a logical extension of the partly bounded function and should meet the needs of those who find it necessary to investigate frequency distributions requiring treatment with a more general formula. The writer is of the opinion that extra-statistical considerations are not only justified as an aid in these investigations, but that the physical conditions influencing any phenomena should always be studied, and the results of such studies should be included in and made a part of the investigation. No other method except that of probabilities, is available in many investigations dealing with problems of water supply, river regulation, and flood control, and to pass by the aids offered by the use of such tools as the material in this paper, would appear to be the poorest of judgment on the part of the engineer who does not avail himself of them.

While the writer does not see any great practical advantage in the use of this new function over the semi-graphical methods heretofore proposed, the advantages in many cases over the older functions used for analytical methods are quite obvious. It would be of interest and value to those who contemplate the use of these functions to have the formulas given for the standard errors of the moments and constants necessary for the solution of the equations. The author is to be commended for his able contribution to the literature of this subject.

F. T. Mavis,[28] Assoc. M. Am. Soc. C. E. (by letter).—The mathematics of statistical analysis is likely to become so intriguing that the objectives and the limitations of the analysis may be obscured by algebraic manipulation and integration. Undue attention to analytical formulation may conceivably lead to tacit assumptions and hypotheses and to conclusions which appear to be contradictory. The author states, for example (in the sentence preceding Table 2), that "* * * it must be remembered that appearance, particularly of a graph plotted on logarithmic probability paper, is no test of goodness of fit," and later, in Example *b,* he states "* * * a glance at Fisher's diagram[30] and at Fig. 1 of this paper is sufficient to show that the latter is at least as good a fit." Back of the first statement undoubtedly lies not only the tacit assumption of something like Pearson's test of goodness of fit,[29] but also the assumption that the type curve chosen must be expressible in equations of a particular form.

---

[28] Associate Director, in Chg. of Laboratory, Iowa Inst. of Hydr. Research; Prof. and Acting Head, Dept. of Mechanics and Hydraulics, State Univ. of Iowa, Iowa City, Iowa.

Under "Graphical Methods," the author appears to have blamed the tools rather than the improper or unskillful use of them in his statement that the use of "probability" paper and other graphical devices is an undesirable practice, and that these methods convey to the eye a simplicity which does not really exist. According to Professor Slade, "the process of using these methods is not essentially different from that of fitting a curve to the data, except for the fact that one is more likely to fit the wrong curve graphically than analytically." To one who has had some practice in using both graphical and numerical methods of curve fitting the foregoing dicta are somewhat disturbing, and the writer would be much interested in the arguments supporting the author's statements.

Admittedly, there are cases in which graphical methods are less convenient than numerical methods, and there are border-line cases in which the choice of the one or the other is largely a matter of personal preference, or the whim of the moment. The person equally skilled in the use of both will ordinarily make his choice between them on the basis of: (1) The limits of precision demanded to be consistent with the precision of the given data; (2) the relative amounts of time required to arrive at a solution by the two methods; and (3) the chance taste of the computer at the moment. It is the writer's opinion that the engineer who has frequent occasion to analyze statistical data would do well to acquire skill in the use of both graphical and numerical (or analytical) methods. It is not unlikely that the crudest of methods—graphical or numerical—will satisfy the engineer who at infrequent intervals follows the simplest procedure described in a book which he finds handy.

Any set of observational data to which statistical methods may be applied, must be considered as a sample which may approximate but never precisely define every larger set of the same data. An arrangement showing the frequencies of values in classes arranged in order is called a frequency distribution. For a given sample and given class intervals there is a unique frequency distribution which may be represented graphically by a frequency polygon, or by a histogram which is made up of frequency rectangles. An estimate of the limit that would probably be approached if the class intervals were made smaller and the number of observations larger, without limit, is represented by the frequency curve—a graphical counterpart of the author's frequency functions. It is to this frequency function that the author is directing his analysis, an analysis which is based naturally on the assumption that the variables are continuous instead of discrete.

---

[29] "Handbook of Mathematical Statistics," by H. L. Rietz, p. 78.

If due consideration is given to the effects of errors in making observations, and if data are reported with a precision consistent with the probable error of a single observation, all hydrologic variables must be considered discrete rather than continuous variables. If increments of the variables represent a constant numerical difference—as in the case of annual rainfall shown in Fig. 2—linear graduations of the variable appear consistent with the data. If increments represent constant percentage differences, as might be anticipated in the case of run-off measurements, logarithmic graduations of the variable would appear to be preferred. A wide variety of regular functional co-ordinates can be devised by trial to represent cumulative frequencies as abscissas if the values of the variable are plotted as ordinates. If graphical methods (see under heading, "Graphical Methods") "* * * convey to the eye a simplicity which does not really exist" is it not equally true that by assuming a continuous function for a small sample of discrete variables that the analysis may be needlessly complicated? Is it good practice to apply to small samples of observations, which are most common in engineering studies, the more elegant methods devised by the statistician on the basis of assumptions of an infinite number of observations of a continuous variable?

The writer does not clearly understand (see Section 7) why "* * * one is more likely to fit the wrong curve graphically than analytically." The statement appears to imply one or more assumptions which are not necessarily true: (1) That the same curve cannot be fitted by graphical as by numerical methods; (2) that the correct curve is known or even determinable; and (3) that the tests of goodness of fit can not be applied, within consistent limits of the data, to either an analytical expression or to its graphical counterpart.

The writer does not wish to imply that the analytical methods described by the author do not have their proper sphere of application, nor that after many more years of records are available they might conceivably be helpful in analyzing rainfall and run-off data. Perhaps by that time the mathematician and the engineer may have discovered even greater simplifications in both graphical and numerical methods.

L. STANDISH HALL,[30] ASSOC. M. AM. SOC. C. E. (by letter).—This paper follows a series of papers, covering the same subject, which have been presented to the Society from time to time. Considering the mathematical nature of the subject-matter, the author has handled the text in a very readable manner.

The curves presented are of a sufficiently flexible nature to fit a given set of data more satisfactorily than any other yet prepared. This is particularly true with regard to maximum and minimum values. However, from the standpoint of logic, rather than statistics, it is evident that many short records of hydrological functions cannot be expanded by any formula to give a reliable indication of the probable happening in a 100-yr or 1 000-yr period.

The author anticipates this difficulty for he states (see "Synopsis") that, "unless the data are very complete, the final results will seldom have meaning because of the magnitude of the probable errors of the parameters involved." In discussing end points he concludes, furthermore, that it may be necessary to "set limits to the problem from extra-statistical considerations." These two quotations state clearly the nature of the difficulty encountered in applying statistical methods to short records. Strictly speaking, it is the writer's opinion, after careful analysis of many records, that the distribution of data cannot be determined with accuracy for a 100-yr period until at least a 200-yr record is available.

---

[30] Chf. Hydrographer, East Bay Municipal Utility Dist., Oakland, Calif.

The point in question can be best illustrated perhaps by an example taken from the record of the seasonal run-off of the Mokelumne River in California. A record (partly estimated from neighboring streams) is available for a period of 39 yr, from 1895–96 to 1933–34. A duration curve drawn from these data is shown in Fig. 4(*a*). This is the curve of natural run-off from 1895–96 to the season, 1933–34, measured and estimated. The mean annual run-off for the 39-yr record is 744 000 acre-ft; but a consideration of rainfall records, which cover about twice the period of time, indicates that the mean seasonal run-off of the Mokelumne River over a longer period of time would be about 800 000 acre-ft. Therefore, undoubtedly, the period of record includes a preponderance of run-off below normal. From Fig. 4(*a*), as drawn, it is probable that the minimum run-off in a 100-yr period can be determined with a greater degree of accuracy than the maximum run-off.

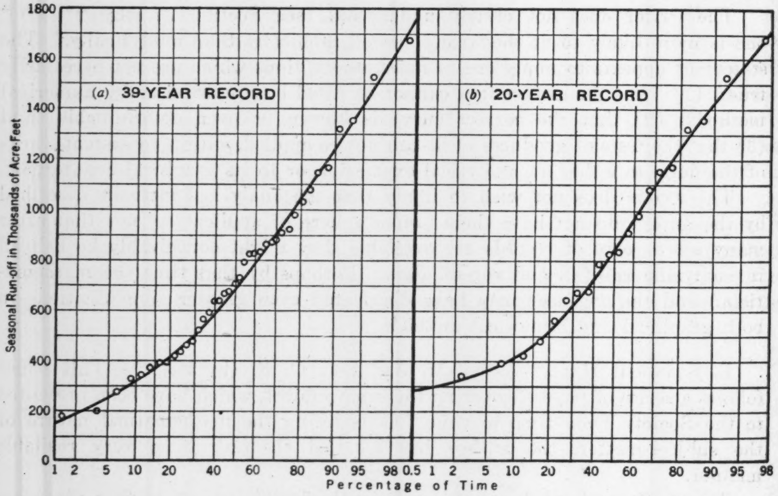

FIG. 4.—MOKELUMNE RIVER AT CLEMENTS, CALIF.; DURATION CURVE OF RUN-OFF FOR THE SEASONAL YEARS ENDING SEPTEMBER 30, 1934.

This is perhaps more evident by comparing the curve in Fig. 4(*a*) with a similar curve prepared from the first 20 yr of record as depicted in Fig. 4(*b*). The latter is the curve of natural run-off from 1895–96 to the season, 1914–15, measured and estimated. From Fig. 4(*a*) it would appear that once in 100 yr a seasonal run-off of less than 150 000 acre-ft could be expected. From Fig. 4(*b*), the minimum in the same period of time is 300 000 acre-ft. There would have been no justification on the basis of the 20-yr record of estimating a minimum of 150 000 acre-ft.

In connection with reservoir studies it is often probable that two, three, or four dry years in succession will create a more serious draft on storage than a single dry year. The average probable minimum yearly flows during such dry periods can be determined readily from the duration curve. The location of the proper percentage can be determined mathematically according to the laws of chance. The probability of several successive occurrences in a period of time is the *n*th root of the period selected. Thus, the two dryest successive years in a 100-yr period would be less than $\sqrt{0.01}$, or 0.10; that is, two years in succession would occur in a 100-yr period of lesser volume than the run-off, which would normally occur once in 10 yr. The average of two successive years can be assumed to be equal to the median point or to the run-off which would occur 5% of the time. Similarly, the average three, four, five, and six successive dry years in a 100-yr period can be found at the ordinates, 11%, 16%, 20%, and 23%, respectively.

The probable dryest periods of annual flow of the Mokelumne River ranging from 1 yr to 6 yr and the actual occurrences based on the 39-yr record in Fig. 4(*a*), and also on the first 20-yr record in Fig. 4(*b*), have been listed in Table 11. It is seen that the year, 1924, was not the dryest year to be expected in 100 yr; neither were the years, 1930 and 1931, the two dryest years in succession to be expected. However, the three years, 1929–31, were about equal to the dryest period of this length to be expected, and the years, 1929 to 1934, were appreciably dryer than the normal 6-yr period to be expected in 100 yr.

TABLE 11.—DRYEST PERIODS OF ANNUAL FLOW OF MOKELUMNE RIVER, RANGING FROM ONE YEAR TO SIX YEARS

Occurrence	39-YEAR RECORD				20-YEAR RECORD			
	Estimated		Measured		Estimated		Measured	
	Percentage from Fig. 4 (*a*)	Mean seasonal run-off, in acre-feet	Seasonal years	Mean seasonal run-off, in acre-feet	Percentage from Fig. 4 (*b*)	Mean seasonal run-off, in acre-feet	Seasonal years	Mean seasonal run-off, in acre-feet
Single year.....	0.5	120 000	1924	182 000	0.5	280 000	1898	346 000
Two years.....	5	250 000	1930–31	319 000	5	360 000	1912–13	408 000
Three years....	11	330 000	1929–31	323 000	11	425 000	1898–1900	528 000
Four years.....	16	380 000	1931–34	400 000	16	475 000	1897–1900	640 000
Five years......	20	415 000	1930–34	407 000	20	520 000	1896–1900	669 000
Six years.......	23	440 000	1929–34	395 000	23	555 000	1898–1903	708 000

If the first 20-yr record is considered alone, it will be noted that the estimated occurrences for all periods from 1 yr to 6 yr are considerable lower than the actual record. This could be accepted as an indication that the dryest cycle of years to be expected had not yet been experienced. This diagnosis was amply borne out by the succeeding nineteen years of record.

In the case of the full 39-yr record, the close agreement between the measured and the estimated occurrence for periods from 3 to 6 yr would indicate that, at present, the minimum year can be determined with a reasonable degree of accuracy. In fact, if a wet cycle of years should follow, the record for 60 yr might indicate a revision of the 100-yr minimum upward.

A method of determining the probable accuracy of the maximum and minimum end-points is a necessary adjunct to the use of probability methods to statistics.

ARNE FISHER,[31] ESQ. (by letter).—In several places in this paper Professor Slade uses such terms as "homograde series," "homograde frequency functions," and "partly bounded functions"; and in Part IV he discusses a certain function which he terms "the most general frequency function" which, in a sense, would seem to imply that this type of function includes all other known types, such as the Gaussian or Laplacean exponential error curve, the Poisson exponential, Gram's series, and the error curves introduced by Kapteyn and Bachelier. It should be noted that the author does not state what he understands by the word, "homograde." The technical terms, "homograde" and "heterograde," were first introduced and defined in the theory of statistics by Charlier and have a perfectly definite meaning.[32] The term, "homograde," as used by Professor Slade apparently stands for something quite different and his so-called "homograde functions" appear to be certain frequency functions defined by Equations (45) or Equation (11) of his paper. These equations are nothing but special cases of the frequency function:

$$y = \frac{1}{n\sqrt{2\pi}}\, e^{-0.5t^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (52)$$

in which, $t = \left[\dfrac{h(x) - m}{n}\right]$, which in the case of $h(x) = x$ reduces to the well-known law of error by Laplace and Gauss.

In 1856, the Danish Minister of Finance, C. G. Andrae, demonstrated[33] that although the spread of "hits" of rifle bullets, when measured in reference to a vertical or horizontal diameter, follow the well-known exponential error law, it will be found, on the other hand, that the spread of the hits when measured from the center of the target will be characterized by the following skew frequency curve:

$$P(x) = \frac{2x}{a^2}\, e^{-0.5x^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (53)$$

where $P(x)$ is the probability that a bullet will strike a target at a distance, x, from the center. Furthermore, if $P_1(x)$ is the normal frequency or probability curve,

---

[31] Actuary, Western Union Telegraph Co., New York, N. Y.

[32] "Mathematical Theory of Probabilities", by Arne Fisher, p. 128, Macmillan Co., New York, 1930.

[33] "Bestemmelsen af Skudsikkerheden ved Skydning mod verticale Skiver", by C. G. Andrae, 1856.

$$P_1(x) = \frac{1}{n\sqrt{2\pi}}\, e^{-0.5x^2 : n^2} \ldots\ldots\ldots\ldots\ldots\ldots (54)$$

the probability curve for, say, x^2, will differ from Equation (54)[34].

In general, therefore, if a certain statistical variate, x, is normally distributed (that is, if it is subject to the Laplacean probability curve, or the error law of Gauss), a function of x, say $H(x)$, will not necessarily be distributed normally. On the other hand, it is also true that if the variate, x, is not normally distributed, a function of x, say $h(x)$, may be so distributed. Therefore, it should be possible, at least in theory, to throw a skew or non-normal curve into normal form through a proper transformation of the variate, x.

As a matter of fact, in 1889[35], Thiele, a Danish astronomer and actuary, discussed the general problem of determining the frequency curves, not only for x but for various functions of x. He mentions that, if the distribution of the variate, x, as actually observed, is found to be skew, or to deviate from the normal probability curve, x may be considered as a "fictitious" observation of the "pseudo-normal" variate, $t = h(x)$, which latter function is supposed to follow the Gaussian error law; that is, if $t = h(x)$ is distributed according to a known normal error law of exponential form, it is possible to find the frequency distribution of the inverse function, $x = g(t)$.

A brief outline of some of the more elementary parts of Thiele's work (based on a communication to the writer from the late Dr. J. P. Gram, in 1903) is, as follows (for numerical details see Table 18):

1.—Arrange the observed frequencies, $F(x)$, in class intervals of the variate, x.

2.—Accumulate the values, $F(x)$ (that is, in the form $\sum\limits_{-\infty}^{x} F(x)$), successively, or step by step, from lower to upper limits of class intervals.

3.—Calculate the accumulated relative frequencies, or $\sum\limits_{-\infty}^{x} \phi(x) = \dfrac{\sum\limits_{+\infty}^{x} F(x)}{N}$,

in which, $\sum\limits_{-\infty}^{\infty} F(x) = N$ equals the size of the observed sample; that is, the total number of observed individuals.

4.—The curve under Step (3) will be a monotonely increasing function, gradually rising from zero to an upper limit which never can be greater than 1.

5.—It is evident, therefore, that a unique, or a one-to-one, correspondence exists between $\sum\limits_{-\infty}^{x} \phi(x)$ and the probability integral, $I(t) = \int_{-\infty}^{t} e^{-0.5t^2}\, dt$, so that to every value of x in $\sum\limits_{-\infty}^{x} \phi(x)$ there will be a corresponding value of t in $I(t)$.

---

[34] "The Mathematical Theory of Probabilities," by Arne Fisher, 1930, p. 236.

[35] "Almindelig Iagttagelseslaere" ("A General Doctrine of Observations"), by T. N. Thiele, 1889.

6.—Plot on co-ordinate paper the values of t corresponding to x. The form of the graph or curve drawn through these points will give a general idea of the function of x that will be normally distributed, although x itself may not be normally distributed.

7.—The functional expression of $t = h(x)$ may assume a great variety of forms, some of which are:

$$t = ax + b = (x - M) : \sigma \ldots\ldots\ldots\ldots\ldots\ldots\ldots (55)$$

which is the usual form of t in the exponential curve of error;

$$t = a_0 + a_1 x + a_2 x^2 + \ldots a_n x^n \ldots\ldots\ldots\ldots\ldots (56)$$

special forms of which are ax^2, ax^3, etc.; and, $t = \log x$, or,

$$t = [\log (x - a) - m] : n \ldots\ldots\ldots\ldots\ldots\ldots\ldots (57)$$

8.—When it is known that there is both a lower finite limit,, x_0, and an upper finite limit, x_n, the following form is very useful:

$$t = h(x) = \left[\log \left(\frac{x - x_0}{x_n - x} \right) - m \right] : n \ \ldots\ldots\ldots\ldots (58)$$

A correlation coefficient, for instance, has a lower limit of -1 and an upper limit of $+1$. A probability can never be less than zero or greater than 1. At any one instant, the busy selectors over a telephone exchange can never be less than zero or greater than the number of subscribers. (In Poisson's formula there can be theoretically an infinite number of calls.)

Among these various transformations the writer first proposes to consider Equation (57) because it is the one that he has discussed somewhat in detail elsewhere and the one which Professor Slade has criticized. Under the heading, "Transformations of the Variate," the author cites Equation (10) as the definition of a new generic function credited to the writer. This statement is in error; no where has the writer made use of the function as claimed in Professor Slade's Equation (10). The generator that the writer used[10] was of the form:

$$\phi_0 (x) = \frac{N}{n \sqrt{2\pi}} e^{-0.5[\lambda(x)]^2} \ldots\ldots\ldots\ldots\ldots\ldots (59)$$

in which, $h(x) = \left[\frac{\log x - m}{n} \right]$.

Moreover, the writer has emphasized the fact that the logarithmic transformation in question, presupposes a lower limit, a, located at a distance of u units from the mean value of the variate (or first-order semi-invariant, $\lambda_1(x)$, of x) and defined by the relation, $\lambda_1(x) - u = a$. The value of u is the real root in the cubic equation,[36]

$$\lambda_3 u^3 - 3 \lambda_2^2 u^2 - \lambda_2^3 = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (60)$$

in which, λ_2 and λ_3 denote the semi-invariants of second and third order.

---

[36] "The Mathematical Theory of Probabilities," by Arne Fisher, 1930, p. 239.

The logarithmically transformed generic function, as the writer uses it, becomes, therefore, Equation (59), with $h(x) = \left[\frac{\log(x - a) - m}{n}\right]$, and not the function that Professor Slade attributes to the writer in his Equation (10).

This feature is important in connection with the author's "partly bounded function," which he defines by Equation (11). In introducing this allegedly "new" function Professor Slade writes,

> "Notice, in the first place, that Equation (11) is similar to the logarithmically transformed function, Equation (10), differing from it only in the power, c^2, to which it is raised. The difference is fundamental, however. It is just this added parameter, c, that makes Equation (11) more than a 'normal' for the logarithms of the variate and which brings about a remarkable simplification of the formulas. It is this c, indeed, that makes Equation (11) a true generalization of Equation (1)."

In this case the author has magnified the mathematical symbol, c, out of all proportion; his Equation (11) is identical to the logarithmically transformed generator in Equation (59) which he has criticized in his discussion of some of the writer's work.

As proposed by Professor Slade in Equation (11) his function is of the form:

$$y = A\ e^{-[g(x)]^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (61)$$

in which, $g(x) = c\ [\log(x + b) + \log d]$; whereas the generator, as the writer has used it, is of the form of Equation (59), with $h(x) = \left[\frac{\log(x - a) - m}{n}\right]$, which simply states that the quantity, $\log(x - a)$, is normally distributed around a mean value, m, with a dispersion (or standard deviation) equal to n.

This generator is algebraically identical to the "partly bounded function" in the paper by Professor Slade; in fact, $A = N\ (n\sqrt{2\pi})^{-1}$; $c^2 = 1:2n^2$; $\log d = -m$; and, $b = -a$ (or u). The author's criticism of the type of generator in Equation (59), therefore, also applies to his own "partly bounded function" (Equation (11)).

By way of illustration it may be of interest to apply the methods advocated by the writer to Professor Slade's "Example a." The author uses moments, whereas the writer has preferred to use semi-invariants, which, as a rule, are easier to handle in numerical calculations. However, when the moments are taken around the mean as origin, it is found that the first, second, and third moments, μ_1, μ_2, and μ_3, are equal to the semi-invariants, λ_1, λ_2, and λ_3; therefore, $\mu_1 = \lambda_1 = 2.335$; $\mu_2 = \lambda_2 = 1.442$; and $\mu_3 = \lambda_3 = 3.607$.

The equation for determining the value of u is, therefore: $3.607u^3 - 3\ (1.422)^2\ u^2 - 1.442^3 = 0$; or,

$$3.607\ u^3 - 6.238\ u^2 - 2.998 = 0 \ldots\ldots\ldots\ldots\ldots (62)$$

for which the real root is found to be $u = 1.948$ (with $u^2 = 3.795$). Consequently, the lower limit, a, equals $2.335 - 1.948$, or 0.387.

Moreover,[36] $n^2 = \log (1 + 1.442 : 3.795) = \log 1.381 = 0.323$; $n = 0.5683$; $m = \log (1.948) - 1.5\ (0.323) = 0.6668 - 0.4845 = 0.1823$; and, $N = 251 : e^{0.1823 + 0.1615} = 251 : 1.416 = 177.93$; so that finally:

$$\phi_0\ (x) = \frac{177.93}{0.5683 \sqrt{2\ \pi}}\ e^{-0.5[h(x)]^2} = \frac{313.1}{\sqrt{2\ \pi}}\ e^{-0.5[h(x)]^2} \quad \ldots\ldots(63)$$

in which, $h(x) = \left[\dfrac{\log (x - 0.387) - 0.1823}{0.5683}\right]$.

The computation of the ordinates is given in Table 12. It will be noticed that the final results are exactly the same as those in Table 4 and are reached with less effort than that involved in the method proposed in the author's paper. Professor Slade's Objection (*a*), under the heading, "Transformations of the Variate," can be met by the statement that his (Slade's) method requires the identical solution of the same type of cubic, as expressed in his own Equation (24). Moreover, it seems that his (Slade's) theoretical development, involving Equations (12) to (42), is unnecessarily unwieldy and considerably more complicated than the writer's (Fisher's) theory.

TABLE 12.—COMPUTATIONS FOR DETERMINING ORDINATES OF FREQUENCY CURVE (SEE TABLE 4)

x (1)	$\log (x - 0.387)$ (2)	(2)$-$0.182 (3)	(3):0.568$=t$ (4)	$\phi_0\ (t)$ (5)	313.1(5) (6)
1	-0.489	-0.671	-1.181	0.1986	62.2
2	0.478	0.296	0.521	0.3483	109.1
3	0.960	0.778	1.370	0.1561	48.9
4	1.285	1.103	1.942	0.0605	18.9
5	1.529	1.347	2.371	0.0240	7.5
6	1.725	1.543	2.717	0.0099	3.1
7	1.889	1.707	3.005	0.0044	1.4
8	2.030	1.848	3.254	0.0020	0.6
9	2.153	1.971	3.470	0.0010	0.3
10	2.263	2.081	3.664	0.0005	0.2

In "Example *b*" the author has quoted certain data from the writer's investigations and states "that the work required to fit these data by the present [Slade's] method is quite negligible compared to that which Fisher must do to obtain a result that is 'satisfactory for all practical purposes'."

In the light of what has been said before in reference to the writer's own Equation (59), which is algebraically identical to, and easier to handle than, the author's "partly bounded function," the foregoing and somewhat dogmatic assertion by Professor Slade becomes invalid in so far as the generating function, $\phi_0(x)$, is concerned.

In Table 13, the values of the symbols, *b*, *c*, and *d*, as used by Professor Slade, are compared with the corresponding values of the symbols, *a* (or *u*), *m*, and *n*, that enter into the formulas that the writer has used.[37] Referring to Column (3), Table 13, $\lambda_1\ (x) - u = a$. If the origin is taken at the mean, or at $\lambda_1(x)$, it is found that $\lambda_1(x) = 0$, or $a = -u$.

TABLE 13.—COMPARISON OF SYMBOLS—SLADE AND FISHER METHODS

SLADE		FISHER		Remarks
Symbol (1)	Value (2)	Symbol (3)	Value (4)	(5)
b	6.118	a (or $-u$)	6.118	Identical
c	1.681	n	0.4205	....
c^2	2.826	$1:2n^2$	2.826	Identical
d	0.2131	m	1.5462	....
log d	—1.5462	$-m$	—1.5462	Identical

The logarithmically transformed variate (on the basis of age intervals of 1 yr) becomes,[87]

$$t = h(x) = [\log (x - 13.1) - 2.645] : 0.420 \ldots\ldots\ldots\ldots (64)$$

with a generating function of the form:

$$\phi_0 (x) = \frac{1}{0.420 \sqrt{2\pi}} e^{-0.5[h(x)]^2} \ldots\ldots\ldots\ldots\ldots (65)$$

in which, $h(x) = \left[\dfrac{\log (x - 13.1) - 2.645}{0.420}\right]$.

TABLE 14.—COMPUTED MID-ORDINATES (SEE TABLE 5)

Ages (inclusive) (1)	Observed frequencies (2)	Computed mid-ordinates (3)	Ages (inclusive) (1)	Observed frequencies (2)	Computed mid-ordinates (3)	Ages (inclusive) (1)	Observed frequencies (2)	Computed mid-ordinates (3)	Ages (inclusive) (1)	Observed frequencies (2)	Computed mid-ordinates (3)
13 to 15	1	1	31 to 33	2 711	2 798	49 to 51	272	260	67 to 69	17	19
16 to 18	9	31	34 to 36	1 918	2 064	52 to 54	186	166	70 to 72	14	13
19 to 21	745	831	37 to 39	1 339	1 428	55 to 57	141	107	73 to 75	3	8

25 to 27	3 828	3 486	43 to 45	533	624	61 to 63	72	45	79 to 82	....	4
28 to 30	3 801	3 426	46 to 48	380	405	64 to 66	43	29	> 83	......	6

The computed mid-ordinates, using the correctly computed generating function (Equation (65)), are listed in Table 14.

It is easily recognized that the generating function itself (or Professor Slade's "partly bounded function") is not powerful enough to represent the observations (which are not only skewed, but peaked or "top heavy"). Indeed this becomes evident if one computes the fourth-order semi-invariant, which serves to characterize the peaked character, or the flatness, of the curve. For this very reason it becomes necessary to resort to a more refined graduation by means of a Gram series of the form:

$$c_0 \phi_0 (x) + c_3 \phi_3 (x) + c_4 \phi_4 (x) \ldots\ldots\ldots\ldots\ldots (66)$$

in which, $\phi_0 (x)$ is the generating function as computed in Equation (65) and

---

[87] "The Mathematical Theory of Probabilities", by Arne Fisher, p. 258 (m + log 3 = 2.645).

$\phi_3(x)$ and $\phi_4(x)$, its third and fourth-order derivatives. This further graduation may be carried out by least squares,[37] and results in the distribution shown in Table 15.

TABLE 15.—FREQUENCY DISTRIBUTION BY GRAM SERIES

Ages (inclusive) (1)	Computed frequencies (2)	Ages (inclusive) (1)	Computed frequencies (2)	Ages (inclusive) (1)	Computed frequencies (2)	Ages (inclusive) (1)	Computed frequencies (2)	Ages (inclusive) (1)	Computed frequencies (2)
13 to 15	0	28 to 30	3 707	43 to 45	519	58 to 60	88	73 to 75	21
16 to 18	72	31 to 33	2 899	46 to 48	342	61 to 63	66	76 to 78	16
19 to 21	696	34 to 36	1 996	49 to 51	233	64 to 66	50	79 to 82	13
22 to 24	2 369	37 to 39	1 284	52 to 54	163	67 to 69	38	>83	24
25 to 27	3 714	40 to 42	816	55 to 57	118	70 to 72	29	....	....

Fig. 5, which demonstrates the superiority of the Gram series, affords a comparison between: (1) The original observations; (2) the computed frequencies based on a single generator, Equation (65); and, (3) the frequencies as computed from a Gram series. An application of the so-called test of "goodness of fit," as devised by Pearson and R. A. Fisher also shows that a single generating function does not suffice to describe the observations. The test for "goodness of fit" (which might better be termed a test for "poorness of fit") gives altogether too much weight, however, to the infrequent and rare observations toward the ends of the curve. A superior, although rather lengthy, test is offered through the so-called "error critique" by Thiele. This "error critique," which utilizes an ingenious system of weighting, also shows the superiority of the Gram series.

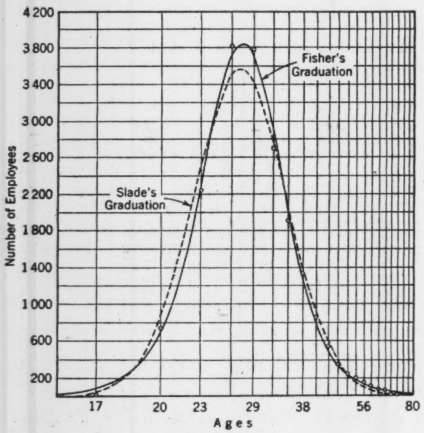

FIG. 5

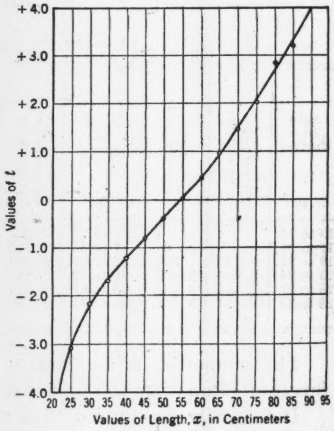

FIG. 6

In reference to "Example *c*," giving forty-nine individual observations on rainfall, the writer recommends the following simple procedure in preference to the tedious method proposed by Professor Slade. If the Naperian logarithms of the forty-nine individual measures of rainfall are arranged in intervals of 0.1, the resulting frequency values are as shown in Table 16.

TABLE 16.—FREQUENCIES OF LOGARITHMS OF INCHES OF YEARLY RAINFALL

Logarithm of rainfall, z (1)	$F(z)$ (2)	Logarithm of rainfall, z (1)	$F(z)$ (2)	Logarithm of rainfall, z (1)	$F(z)$ (2)
3.4 to 3.5	2	3.8 to 3.9	11	4.1 to 4.2	2
3.5 to 3.6	0	3.9 to 4.0	14	4.2 to 4.3	1
3.6 to 3.7	7	4.0 to 4.1	4	> 4.3	0
3.7 to 3.8	8	....	..	....	...

An elementary and rapid calculation yields the value, $\lambda_1(z) = M = 3.852$, for the mean, and $\sqrt{\lambda_2} = \sigma = 0.164$ as the value for the dispersion (or standard deviation). The simple normal exponential frequency curve, therefore, takes on the form of Equation (59) thus,

$$\phi_0(x) = \frac{49}{0.164\sqrt{2\pi}} e^{-0.5t^2} \qquad (67)$$

in which, $t = \left[\frac{\log x - 3.852}{0.164}\right]$. The resulting values, comparable to those in Table 7, are listed in Table 17.

TABLE 17.—COMPUTATION OF FREQUENCIES TO COMPARE WITH TABLE 7

* Taken from "Table of Probability Integral," in "Statistical Methods," by C. B. Davenport, Table IV, p. 119, John Wiley & Sons, New York, 1904.

The fact that the logarithms of the measures of rainfall have been regarded as the observed quantities leads immediately to the Laplacean probability function, or normal error curve, without going through the more complicated calculations of the logarithmic transformation. This fact, however, leads one to question the undue stress that Professor Slade has put on the existence of upper and lower limits, situated within a finite range, instead of extending from minus infinity to plus infinity in the normal exponential error law. If one were to insist on definite upper and lower limits of the direct measures of rainfalls, why should one not also insist on definite limits, or a finite range of variation, for the logarithms of the measures?

The writer has referred briefly to Thiele's "pseudo-normal" variates, and has mentioned, as a special case, the transformation,

$$t = h(x) = \left[\log \left(\frac{x - x_0}{x_n - x} \right) - m \right] : n \text{ .... } (68)$$

in which, x_0 and x_n represent the upper and lower limits of the observations. This transformation can be shown to be identical to that proposed by Professor Slade in his "Most General Function," Equation (45*a*). To be sure the latter contains apparently five constants as against four in Equation (68), but the fifth constant, corresponding to p in Equation (45*a*), is contained in the value of m. Moreover, in Professor Slade's Equation (45*d*) it appears that the constant, p, is expressed in terms of the other constants, so that after all there are only four constants.

"Example *d*," which Professor Slade has chosen to illustrate his "most general frequency function" is too fragmentary to be of much use. No observed statistical data are given, except in a rough graphical representation in Fig. 3 of the paper.

As an illustration of this function and also of the identically same type of transformation (Equation (68)) mentioned by Gram, the writer presents, in

Table 18, Columns (1) and (2), some observations[38] by Dr. Giltay, of Wageningen, Holland, on lengths, in centimeters, of 1 008 oat stalks.

Column (1) shows the length, in centimeters, of the 1 008 stalks; Column (2) gives the frequencies, $F(x)$, in the intervals shown in Column (1); Column (4) contains the accumulated absolute frequencies; Column (5) lists the accumulated relative frequencies; and in Column (6) are the values of t in the probability integral, $I(t)$, corresponding to x in $\sum_{-\infty}^{x}\phi\,(x)$. This value of t is found by entering the table of the probability integral inversely which explains the heading for Column (6) as the anti-probability of $I(t)$.

The points, t, corresponding to x are plotted as small circles in Fig. 6. If a linear relation, $t = h(x) = (x - M):\sigma$, is assumed, $t = (x - 54):11.8$, approximately. However, this gives a poor fit, because a glance at the curve, $t = h(x)$, shows that it has a pronounced point of inflection in its central region and tapers downward more rapidly than the straight line; and, likewise, it rises more rapidly upward than the straight line. Consequently, the normal error curve that implies a linear relation does not apply to the observations as they stand. The geometrical form of $t = h(x)$, moreover, leads to the assumption of finite upper and lower limits, or to postulate that,

$$t = h\,(x) = \left[\,\log\left(\frac{x - x_0}{x_n - x}\right) - m\,\right] : n \;\ldots\ldots\ldots\ldots (69)$$

The next step, therefore, is to estimate the numerical values of these upper and lower limits, or to find an approximation of x_0 and x_n. It is possible to do so by several algebraic approximations; but this is a tedious process, and it is preferable to use graphical methods of which a great variety is available. A very rapid process has been suggested by the Netherlands mathematician, M. J. Van Uven.[38] An application of this process leads to the choice of x_0 as 0 and x_n as 95, so that,

$$t = h\,(x) = \left[\,\log\left(\frac{x}{95 - x}\right) - m\,\right] : n \;=\; k \log\left(\frac{x}{95 - x}\right) + c \,..(70)$$

The calculation of the logarithms of the fractions, $x:(95 - x)$, is shown in Columns (7), (8), and (9), of Table 18.

The next step is now to find the values of the constants, k and c (or of m and n), in Equation (70). This is most easily done by the method of least squares. If the interval from $x = 35$ to $x = 70$ (in which the majority of the observations fall) is chosen, the anti-probability of $I(t)$ as shown in Column (6), Table 18, may be considered as an observed value of t that is to be expressed by the linear relation,

$$t = k \log\left(\frac{x}{95 - x}\right) + c \;\ldots\ldots\ldots\ldots\ldots\ldots (71)$$

The coefficients of k, that is,

$$\log\,[x:(95 - x)] = a_x \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots (72)$$

---

[38] Koninklijke Akademie Van Wetenschappen te Amsterdam, Vol. 19, No. 4, pp. 533-545, from which the present example relating to oat stalks is taken.

are given in Column (9), Table 18, and 1.000 may be taken as a provisional or preliminary value of c. Hence, the following schemata of observation equations are obtained:

a_x	c	$o(x)$	a_x	c	$o(x)$
−0.234	1.000	−1.696	0.138	1.000	0.015
−0.138	1.000	−1.248	0.234	1.000	0.487
−0.046	1.000	−0.803	0.336	1.000	0.994
0.046	1.000	−0.391	0.447	1.000	1.491

From these observation equations one finds (in the notation of Gauss) that: $[aa] = \Sigma a^2 = 0.465$; $[ac] = \Sigma ac = 0.783$; $[ao] = \Sigma ao = 1.704$; $[cc] = \Sigma c^2 = 8.000$; and, $[co] = \Sigma co = -1.151$. Consequently, $0.465\,k - 0.783c = 1.704$; and, $0.783\,k + 8.000c = -1.151$; or $k = 4.6786$ and $c = -0.6018$. Therefore, $n = (4.6786)^{-1} = 0.214$, and $m = 0.6018 : 4.6786 = 0.129$; or t reduces to:

$$t = \left[\log\left(\frac{x}{95 - x}\right) - 0.129\right] : 0.214 \qquad \text{...........(73)}$$

The calculation of the graduated curve proceeds now (see Columns (10) to (15)) as a simple continuation of Columns (1) to (9) of Table 18. The detailed calculations are self-explanatory, and the final column (Column (14)) which gives the graduated curve, shows a reasonable agreement with the observed and ungraduated data in Column (2), or Column (15). (See Fig. 7.) The same curve type has been discussed by Van Uven, and it is of interest to compare his form with Equation (71). Van Uven writes t as,

$$t = \lambda \log\left[\left(\frac{x - x_0}{x_n - x} : \frac{x_m - x_0}{x_n - x_m}\right)\right] \qquad \text{.............(74)}$$

in which, x_m, a fifth constant, analogous to the constant, p, in Professor Slade's Equation (45a), equals the value of the median of the observations. It is evident that the quantity, $\log\left(\frac{x_m - x_0}{x_n - x_m}\right)$, must fall very close to the value of m in Equation (69), because of the fact that t is assumed to be normally distributed, which implies that the mean value, m, coincides with the value of t that corresponds to the median, x_m, of the observations. The median of the observed values of $F(x)$ falls close to 54.5 cm, so that $\log\left(\frac{x_m - x_0}{x_n - x_m}\right) = \log\left(\frac{54.5}{40.5}\right) = 0.1289$, which checks with the previously calculated value of $m = 0.129$.

The restriction of Van Uven to let the mean in the transformed curve equal the particular value of t that corresponds to the median of the observations is analogous, although not equivalent, to the introduction of the author's constant, p, to make the second moment of the final curve agree with that of the statistics, which at its best is nothing more than a kind of artificial *tour de force.*

In the opening paragraphs of his "Synopsis" Professor Slade refers to "a justification for the introduction of a new function in a field that literally teems with such studies." Enough has probably been said in the preceding paragraphs to demonstrate that there is little, if any, newness in the formulas presented; they are, to all practical purposes, identical with those known from the old methods of logarithmic transformations of the variate.

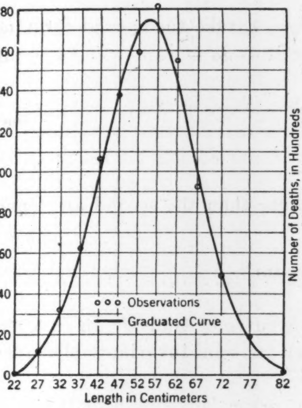

FIG. 7

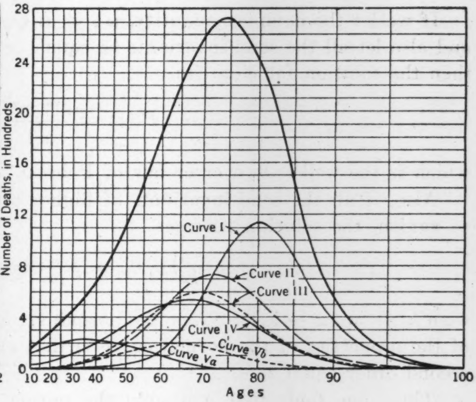

FIG. 8

All such methods go back to Thiele, who always took a critical attitude to the Gaussian law of error with its implied postulate of the arithmetic mean as the most probable value. As early as 1866, Thiele introduced the alternative postulate of the geometric mean as the most probable value, thus antedating McAllister, Fechner, Pearson, and other writers by many years.[89] Thiele's investigations led him to the obvious fact that if the geometric mean of the observations yields the most probable value, the arithmetic mean of the logarithms of the observations must yield the most probable value of the logarithms of the observations, so that if the logarithms of the observations are assumed to be normally distributed, a law of error can be found for the observations themseleves by a logarithmic transformation of the variate. Such a law must necessarily lead to the geometric mean of the observations as the most probable value.

In the text following Equation (7) Professor Slade states "in Thiele's solution, $\phi(x)$ is given as a definite integral which, unfortunately, cannot be integrated; so that the net result is an elegant mathematical process which ultimately gets nowhere."

---

[89] "The Mathematical Theory of Probabilities", by Arne Fisher, p. 288.

The solution to which the author refers is the one in which the frequency function is expressed as a definite integral equation of the form:

$$\phi\,(x) = \frac{1}{2\,\pi}\int_{-\infty}^{\infty} e^{h(\omega i)}\, e^{-x\omega i}\, d\,\omega \;\ldots\ldots\ldots\ldots\ldots\ldots(75)$$

in which,

$$h\,(\omega\, i) = \frac{\lambda_1}{1\,!}\, i\,\omega + \frac{\lambda_2}{2\,!}(i\,\omega)^2 + \ldots + \frac{\lambda_n}{n\,!}\,(i\,\omega)^n$$

If we let the complex quantity, $\omega\, i = \omega\sqrt{-1}$, take the special form, ω, and also let all the semi-invariants be equal, or $\lambda_1 = \lambda_2 = \lambda_3 = \ldots \lambda_n = m$; then the solution for $\phi(x)$ is:

$$P\,(x) = \frac{e^{-m}\, m^x}{x\,!} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(76)$$

which is the well-known error law of Poisson.[40]

Also, if all the semi-invariants of higher order than the second are found to vanish, the solution becomes,

$$\phi_0(x) \;=\; (2\pi\,\lambda_2)^{-0.5}\, e^{-h(x)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots(77)$$

with $h(x) = (x - \lambda_1)^2 : 2\lambda_2$, or the normal error curve of Gauss.[41] In fact, one of the properties of the normal curve is that all its semi-invariants above the second order equal zero.

Thus, one finds that, not only the normal error law, but also Poisson's celebrated exponential, are contained as special cases in Thiele's general functions.

By resorting to an expansion in Gram's series and letting,

$$\phi(x) \;=\; c_0\;\phi_0(x) \;+\; c_1\;\phi_1(x) \;+\; c_2\;\phi_2(x) \;+\ldots c_n\;\phi_n(x)\ldots\ldots(78)$$[42]

one can also solve Thiele's integral equation and use the solution for the numerical determination of the constants, *c*, in the Gram expansion, where $\phi_0(x)$ is the normal or Laplacean error curve in Equation (77).

Of course, as Professor Slade points out, Thiele's general formula may contain other functions than frequency functions. To the writer this long and well-known fact actually enhances rather than detracts from the value of Thiele's work, for the more general a formula is, the greater is its applicability in mathematical analysis. Professor Slade, on the other hand, uses this circumstance as a criticism by stating that Thiele's solution is "too general" for what he somewhat ambiguously terms "ordinary purposes." Such an argument can scarcely be considered as mathematically sound. If accepted, it would imply, among other things, that a Fourier series should be considered as inferior to a Taylor power series, although the Fourier series is able to express all functions that can be expanded by Taylor's formula and many other functions as well.

---

[40] "The Mathematical Theory of Probabilities," by Arne Fisher, p. 265.

[41] *Loc. cit.*, p. 198.

[42] *Loc. cit.*, pp. 209–210.

The same argument of being "too general" is again used by Professor Slade in his criticism of Gram's series. He states also that "if $\phi(x)$ deviates appreciably from the normal curve, $\phi_0(x)$ (or is markedly skew), it may take thousands of terms to get even a fair representation." The writer doubts this statement. Of course, if one were foolish enough to select a generating function that did not even remotely resemble the rough observations, one might drop such an attitude of skepticism; but, as emphasized both by Thiele and Gram, the choice of the generating function is to be guided by the observations themselves. For instance, one should not always let the mean and the dispersion in the generator be equal to the mean and the dispersion of the observations. In greatly skewed or one-sided distributions, such as the classical example of *Ranunculus Bulbosus* by deVries,[43] the variate in the normal generator should not be taken as:

$$t = (x - 0.631) : 0.958 \dots\dots\dots\dots\dots\dots (79)$$

but as,

$$z = [\log (x - 4) - 0.044]\ 0.544 \dots\dots\dots\dots\dots (80)$$

and Gram's series should be written as:

$$F(x) = c_0\ \phi_0(z) + c_1\ \phi_1(z) + c_2\ \phi_2(z) + \dots\dots\dots\dots (81)$$

Furthermore, the objection toward the possible occurrence of negative frequencies mentioned by Professor Slade can easily be overcome if, like Thiele and Charlier, one were to write the frequency function as,

$$F(x) = e^{\Sigma a_i (x)^i} = e^{\Sigma c_i H_i(x)} \dots\dots\dots\dots\dots\dots (82)$$

(for $i = 0, 1, 2, 3, \dots . n$), in which, $H_i(x)$ represents the Hermite functions of the order, i. Taking the logarithms on both sides of Equation (82):

$$c_0 + c_1\ H_1(x) + c_2\ H_2(x) + \dots c_n\ H_n(x) = \log F(x) \dots\dots\dots (83)$$

Multiplying both sides of Equation (83) with the ith derivative of the generator, $\phi_0(x)$, and integrating over the entire range:

$$c_i \int_{-\infty}^{\infty} H_i\ (x)\ \phi_i\ (x)\ dx = c_i\ (-1)^i\ i! = \int_{-\infty}^{\infty} \log F\ (x)\ \phi_i\ (x)\ dx$$

or,

$$c_i = \frac{(-1)^i}{i\,!} \int_{-\infty}^{\infty} \log F\ (x)\ \phi_i\ (x)\ dx \dots\dots\dots\dots\dots (84)$$

for $i = 0, 1, 2, 3, \dots . n$.[44]

---

[43] "The Mathematical Theory of Probabilities", by Arne Fisher, p. 226.

[44] *Loc cit.*, pp. 201–202.

The determination of the constants in the series through this method will never result in negative frequencies. In fact, the method outlined herein is one that can be highly recommended for curves of rainfall, especially since excellent tables of the Hermite functions are now available, progressing by intervals of 0.01.

Article 6, Section II, of Professor Slade's paper is devoted to a discussion to prove the self-evident fact that as t approaches 0, or as the skewness vanishes, Equation (11) will converge toward the normal Laplacean curve as a limiting form. In order to show this, the author goes through a lengthy mathematical analysis of limits involving certain results originally presented by the French mathematician, L'Hospital. Of course, such complicated networks of formulas for limits become wholly superfluous under the methods advocated by Thiele because, if the skewness, or (what is the same thing) the third (and higher) order of semi-invariants vanish, an obvious corollary is derived from Thiele's theory that the resulting curve always is of Laplacean normal form.

A most interesting point that Professor Slade has very briefly touched upon is that of compound frequency curves (see "II—The Partly Bounded Function," Requirement (*a*)), a somewhat difficult problem from the standpoint of mathematics, but at the same time the one that is probably the most important in actual practice. Every frequency distribution observed in Nature is really a compound frequency curve, composed of several subsidiary error curves, either of normal or non-normal types.

In this connection, it is of inteest to point to the remark which the French mathematician, Poincare, made to his German colleague, Lindemann; "The mathematicians," Poincare said, "imagine that the law of errors is a fact of observation, and the observers fancy that it is a theorem demonstrated by mathematics." Neither one of these beliefs is true. As a matter of fact, the Russian mathematician, Tschuprov, in discussing whether or not it is possible to demonstrate by means of empirical methods the existence or non-existence of the exponential law of error, reached the conclusion that none of the numerous (and at times vast) collections, derived from precision and astronomical measurements, offers proof as to the actual existence of the postulated Gaussian error law. Tschuprov himself leaned toward the opinion that the observed statistical samples, especially the larger samples, tended to discredit the actual existence in Nature of the celebrated law of error such as had been derived from purely mathematical speculations.

The Danish biologist, W. Johannsen, furthermore demonstrated by means of experimental research work in plant physiology that many of the biological variation curve types, discussed by Galton and Karl Pearson as normal error curves or skew curves, in reality were compound frequency curves, composed of two or more mathematical frequency curves. This important fact led Johannsen to the introduction in biological research of his celebrated "pure lines."

In other places the writer has made use of this idea of compound frequency distributions and "pure lines" in the construction of mortality tables from statistics, giving the deaths by sex, attained ages at death, and cause of death, but without knowing the therewith correlated number of living persons exposed to the risk of death.[45] In a sense this purely synthetic method constitutes a solution to the problem of determining the probable values of a series of proper fractions, where only the numerators are known, but where every one of the denominators are missing. Of course, it is impossible to solve this problem by mere mathematical or quantitative methods. The only approach toward a solution seems to be by means of partly quantitative and partly qualitative methods in the sense that the numerators, which show the observed statistics on death, do not only possess the quantitative attributes of attained ages at death, but also the qualitative attributes of the causes of death. These two elements in combination with certain biological hypotheses make at least an approximate solution possible by means of mathematical synthesis.

In Fig. 8 the result of such a construction is shown in relation to the mortality among Australian males for the period 1907–1915. The compound curve represents the well-known d_x column, or "curve of death," as found in all first-class mortality tables; the subsidiary causal or biological components give the death curves from specified groups of causes of death.

As pointed out by Dr. Raymond Pearl, the synthesis as proposed by the writer moves along entirely different lines than the earlier frequency curve study by Karl Pearson in his interesting volume on "The Chances of Death," for which Dr. Pearl states that "actually there is no slightest reason to suppose that it [Pearson's method] represents any *biological* reality."[46]

Moreover, the synthesis is of so general a nature that it may equally well be applied to engineering problems. Mr. Bassett Jones,[47] for example, has made use of it in the design and construction of high-speed elevators, and it seems to be equally well adapted for the study of rainfall by taking into consideration the therewith related geographical, climatic, and geological elements.

A question which is of the utmost importance to engineers and observers, who usually deal with limited samples, is that of the mean (or probable) errors of the constants or parameters. Earlier formulas for probable errors of the constants in certain types of frequency curves derived by graphical methods[48] are defective because their derivation rests on the implied assumption that the constants are mutually free or uncorrelated. This implication is faulty. The constants in such curves are correlated in the sense that they all depend on the lower (or upper) limits of the variate; in fact, the constants are mathematical functions of the limits, which in the graphical process are chosen subjectively or by the mere aid of the eye, as it were. The least bit of change in such limits will influence the other constants.

The obstacle of correlation between the constants exists also in the logarithmic transformation with a lower limit (or mathematical zero) in the generator as defined by Equation (57). The writer as well as Mr. Sture

Nydell have succeeded, however, in overcoming this obstacle and have been able to give the following approximate formulas for the mean (or standard) errors of u (or a), m, and n:

$$E_m\ (u) = (1 + t)\ t^{-1}\ [(8 + 106t + 332t^2 + 479t^3) : 12s]^{0.5}$$

$$E_m\ (m) = [(4t^{-1} + 54 + 306t + 895t^2 + 1\,598t^3 + 1\,753t^4) : 6s]^{0.5}$$

$$E_m\ (n) = n^{-1}\ [t\ (8 + 106t + 332t^2 + 479t^3) : 12s]^{0.5}$$

in which E = the mean error; s, the number of observations (or size of sample); and $t = \lambda_2 : u^2$.

In Professor Slade's "Example *a*," one finds $\lambda_2 = 1.442$; $u = 1.948$; $t = 0.3800$; $m = 0.1823$; $n = 0.5680$; and $s = 251$, so that $E_m\ (u) = 0.7324$; $E_m\ (m) = 0.5367$; and $E_m\ (n) = 0.2192$, which shows that the value of the logarithmic mean, m, is decidedly uncertain because its mean error is approximately three times the value of m itself.

ARTHUR W. KEMPERT,[49] ESQ. (by letter).—This interesting paper raises several issues which it would be desirable to discuss somewhat in detail. In the first place, the paper bears, in parts, a close resemblance to the earlier works by Thiele, Gram, Jorgensen, and Fisher. Secondly, it raises the moot questions of small samples and chance errors in relation to various pseudographical methods. Last, but not least, there arises the important question as to whether or not the entire problem of the statistical analysis of rainfall, instead of being viewed as a homogeneous (or homograde) mass phenomenon, might not better be thought of as a heterogeneous object and analyzed by the aid of compound frequency curves.

A point very properly emphasized by Professor Slade is that "the use of probability paper and other graphical devices is an undesirable practice," especially when drawn to logarithmic or semi-logarithmic scales. The practice of a graphical process, no matter how carefully and judiciously it may be performed, is not reliable as a rule when applied to a limited number of observations or to a small sample. Investigators who have occasion to use statistical methods should be extremely cautious, therefore, lest they be led astray by the broad claims for some of the graphical schemes as a general procedure for the analysis of small samples. A case in point is the paper by R. D. Goodrich, M. Am. Soc. C. E. (cited by the author) in which the assertion is made[50] that the graphical method proposed "is developed especially for the examination of records consisting of from about 10 to 50 observations."

As an illustration of the danger of applying graphical methods to small samples of observations, the following data relating to some hitherto unpublished investigations on yeast wine cultures may be of interest.

---

[49] Statistical Asst. and Draftsman, Western Union Telegraph Co., New York, N. Y.

[50] *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 42.

A series of 149 samples, each containing 50 individual observations, was taken from certain pure yeast cultures present in a blend of high-grade vintages. The statistical object in question was found to vary from an observed low value of 8 to a high value of about 27. Table 19 gives the frequency distribution in: (1) The 32d sample (chosen at random); (2) a similar distribution for the 87th sample (also chosen at random); and (3) the frequency distribution of all 149 samples combined. If the 32d sample is fitted graphically, choosing the lower limit[51] at 10, the following equation is obtained:

TABLE 19.—FREQUENCY DISTRIBUTION, VARIATIONS IN PURE YEAST CULTURES IN A BLEND OF HIGH-GRADE WINES

Intervals of the variate (1)	Sample No. 32 (2)	Sample No. 87 (3)	149 samples combined (4)	Intervals of the variate (1)	Sample No. 32 (2)	Sample No. 87 (3)	149 samples combined (4)
8 to 10..........	0	0	5	18 to 20..........	8	12	1 644
10 to 12..........	2	0	78	20 to 22..........	3	5	846
12 to 14..........	8	0	615	22 to 24..........	1	2	270
14 to 16..........	15	17	1 742	24 to 26..........	0	1	52
16 to 18..........	13	13	2 195	26 to 28..........	0	0	3
Total..........	..	..	.....	....	50	50	7 450

$$t : 100 = 1 - (10)^{-0.0000224\,(R-10)^{3.355}} \quad \ldots\ldots\ldots\ldots\ldots (85)$$

When fitted to a Gram series:

$$G(x) = 50\,[\phi_0\,(t) - 0.048\,\phi_3\,(t)] \quad \ldots\ldots\ldots\ldots\ldots (86)$$

with $t = (x - 16.2) : 2.624$. The mean error of c_3 (or of -0.048) equals 0.057 and shows that no reliance can be placed on the empirically determined skewness in the small sample of 50. The mean error in the arithmetic mean exceeds 0.7 and the mean error in the dispersion (standard deviation) is greater than 0.3.

The situation is quite different in the case of the combined sample of 7 450 individual observations. This sample can be fitted to a Gram series of the following order (expressed in definite integral form):

$$G(x) = 7\,450 \left[\int_{-\infty}^{t} \phi_0\,(t)\,dt - 0.045\,\phi_2\,(t) \right] \quad \ldots\ldots\ldots (87)$$

in which $\phi_0\,(t)$ is the generating function and $\phi_2\,(t)$ its second derivative, with $t = (x - 17.31) : 2.68$, which results in the frequency distribution given in Table 20, Columns (1) to (3).

The empirically determined skewness of -0.045 has a mean error of only 0.0047, about one-tenth of the magnitude of c_3, which is an indication of its reliability in contradistinction to the small sample of 50 in which the mean error of c_3 was greater than c_3 itself.

---

[51] *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 4, Equation (*A*).

A comparison between the relative frequencies of $\Delta G(x)$ and the corresponding relative frequencies for the small sample (No. 32) as fitted to the Goodrich formula,[51] is given in Columns (6) and (7), Table 20. The two curves are unlike and demonstrate the danger inherent in any attempt to evaluate a presumptive frequency curve from a small sample.

In view of the close correspondence between the 7 450 observations and the Gram frequency curve, many investigators are likely to conclude from purely empirical considerations that the material in question is homogeneous; such an inference, however, would be unwarranted. With the aid of experimental laboratory analysis, based on the concept of Johannsen's "pure lines" and his own theory of probability synthesis, Mr. Arne Fisher[52] has demonstrated that the observed mass phenomenon, instead of being of a single type, actually is composed of three distinctive types, namely, a Bordeaux vintage (Capestang), a Burgundy vintage (Beaune type), and a vintage from the Crimean Peninsula, characterized by the statistical parameters given in Table 21. This leads to a compound frequency curve, such as shown in Table 20, Columns (8) to (12).

TABLE 21.—COMPOUND DISTRIBUTION OF THREE TYPES

Type	Name	Area	Mean	Dispersion	Skewness

A few remarks seem necessary in regard to the difficult problem of the calculation of mean (or probable) errors of the frequency constants. In the case of the regular Gram series this problem offers no serious difficulty because of the orthogonal properties of the individual terms of the series which, in the terminology of Thiele, makes the constants, *c,* mutually free (independent or uncorrelated) of each other.

---

[52] "Frequency Curves," by Arne Fisher, New York, Macmillan Co., 1922.

In the case of the logarithmically transformed frequency functions as described by Professor Slade, and also in the case of a graphical process, there arises, however, the formidable obstacle that the constants are not mutually free, but are bound or correlated, in the sense that their values will depend upon the lower (or upper) limits of the variate. Any change whatever in the positions of these limits will influence the other constants—the *c* and the *d,* in Professor Slade's formula, or in other formulas that depend on lower (or upper) limits.

Because of the fundamental fact that the constants are bound or correlated, it would seem, therefore, that prior attempts[53] to evaluate the mean (or probable) errors largely must be looked upon as failures. The fundamental implications in such proofs are that the constants are not correlated. Proponents of graphical methods admit that "it does not seem possible to derive any formula for the probable error of the index, *c,*"[54] and, in another place, in discussing the errors in the upper and lower limits, it is also stated that "it does not seem possible to derive any formulas applicable to them."[55] Admissions such as those just quoted naturally lead one to regard many graphical methods in a light of skepticism, as it were.

As one of his requirements, Professor Slade states that "the curve must be specifiable completely by moments no higher than the third," and for higher moments "it becomes necessary to search for physical substitutes." This sound advice seems to be in complete accord with the following rules by Thiele[56]: (1) For first and second semi-invariants (or moments) rely exclusively on the observations; (2) for semi-invariants of higher order than the sixth rely exclusively on theory; and (3) for intermediate semi-invariants (or moments) rely partly upon theory and partly upon the observations.

In conclusion, it may be said that some slight inconsistencies have occurred in the author's treatment of his subject. In one place he states that graphical methods "convey to the eye a simplicity which does not really exist," yet under Example *b,* in comparing his own results with those of Fisher, the author employs a rather crude graphical method of comparison. As matters turn out, Professor Slade's graduated curve in Fig. 1 does not provide nearly as good a fit as Fisher's graduation when subjected to Pearson's test of "goodness of fit."

J. J. SLADE, JR.,[57] ESQ. (by letter).—In developing the function presented in his paper the writer has necessarily had to give considerable weight to the partly bounded function because it was by means of his analysis of it that he was able to construct the elements of the totally bounded curve. In his work, however, he has not had occasion to make use of it. This former function is merely a limiting case of the latter, in which one of the bounds becomes infinite, and in the problems that he has considered the bounds, obviously, have been finite. Perhaps one of the reasons that much of the work of statisticians has been unavailable to the engineer for hydrological investigations is that statisticians are interested usually in graduating the middle range of a frequency distribution, the extreme outer 1%, say, of the distribution being of relatively slight importance to them. The hydrologist, on the other hand, is frequently interested mostly in this outer 1% of the range. It is for this reason that one must insist on the determination of the limits of the range. It is absurd for a probability function to give a finite probability to a Noah's flood. In modern times, there simply is not enough energy resident in the atmosphere to produce anything like it.

[53] As, for example, *Transactions,* Am. Soc. C. E., Vol. 91 (1927), pp. 97-102.

[54] *Loc. cit.,* p. 99.

[55] *Loc. cit.,* p. 100.

[56] "The Mathematical Theory of Probabilities," by Arne Fisher, p. 217.

[57] Asst. Prof. of Eng. Mechanics, Rutgers Univ., New Brunswick, N. J.

Equations (45), as given in the writer's paper, are based on an easy generalization of Equations (44). It is apparent, at once, that the factor, p, belongs therein and that it is not merely "a kind of artificial *tour de force*," as Mr. Fisher expresses it. In the paragraph following these equations, the writer states that their form will probably need modification. A more extended analysis has shown that this is indeed the case. Their correct form, when $b < g$, is:

$$z = p\, c \log d \left(\frac{b + x}{g - x}\right) \dots\dots\dots\dots\dots\dots (88a)$$

$$d = \frac{g}{b} \sqrt{\frac{g^2 (\sigma^2 + b^2) - 4\, \sigma^2\, b\, g}{b^2 (\sigma^2 + g^2) - 4\, \sigma^2\, b\, g}} \dots\dots\dots\dots\dots (88b)$$

$$\frac{1}{c} = \sqrt{\log \frac{g^2 (\sigma^2 + b^2) - 4\, \sigma^2\, b\, g}{b^2 (\sigma^2 + g^2) - 4\, \sigma^2\, b\, g}} \dots\dots\dots\dots\dots (88c)$$

and,

$$p = \sqrt{\frac{g - b}{g + b}} \dots\dots\dots\dots\dots\dots\dots (88d)$$

When $b = g$, then,

$$z = \frac{\sqrt{b^2 - 3\, \sigma^2}}{2\, \sigma} \log \left(\frac{b + x}{b - x}\right) \dots\dots\dots\dots\dots (88e)$$

In his discussion Mr. Williams states that "any purely mathematical treatment of stream-flow data presumes at the outset that all the data are equally reliable," and, from this, he infers that there are limitations in the analytical method which are partly absent in the graphical treatment.. The analysis of a physical problem begins when all the data relevant to the problem are known, and these data necessarily include a knowledge of the reliability of the observations. The purely mathematical treatment begins, first of all, with the proper weighting of these observations, for which various methods are well known and widely used. The writer can not agree, therefore, with the idea that the analytical method is inferior to the graphical because the free-hand curve "can be shifted to give more or less weight to certain points."

Mr. Williams' objection to listing the complete set of peaks in a stream-flow record is well taken. In the first place, it is difficult to define a peak, particularly in the range of small flows, as he observes; second, it is difficult to estimate above what datum the peak should be taken (that is, statistically, a peak is an accidental irregularity above a smoothed hydrograph, and it is difficult to smooth the hydrograph properly); and, third, peaks are not uncorrelated quantities and, consequently, a simple analysis of their distribution is not possible. In presenting this paper the writer limited himself to the analysis of the generalized probability function, and he did not attempt to offer a method for the analysis of stream-flow characteristics. The illustration of the peaks of the Tennessee River record was given merely to show that an extremely skewed and platykurtic distribution could be closely fitted by means of this curve. Using the corrected Equations (88) and an estimate of the extreme flood (415 000 cu ft per sec) based on the following method, a much closer fit is obtained.

The use of the partial series of peaks above the "one-year flood" is open, at least statistically, to a fourth objection, namely, that an error, which may be serious, is introduced in assigning a probability to the "one-year flood." Because of the indeterminacy of this error the writer has not been able to make an estimate of the reliability of the probabilities obtained from a curve fitted to such series.

The writer concurs with Mr. Foster's opinion that Pearson's curves satisfy all the desiderata presented in his paper for a generalized frequency curve, provided all the types in Pearson's development are included. Except in the border cases one type cannot be substituted for another, and in order to select the proper type for a given distribution it is necessary to use Pearson's criterion or something equivalent (implying the computation of moments through the fourth). The statistical characteristics beyond the standard deviation computed from small samples (say, samples with less than 100 items) are so unreliable that they are useless. This statement needs no mathematical proof (although such could be readily given); the experiment may be tried of drawing small samples from a fairly large population, and, from these samples, the mean, standard deviation, and the skewness may be computed. It will then be found that, although the first two characteristics will vary, they will show a remarkable uniformity, nevertheless, compared with the wide fluctuations in the latter.

Table 22 meets the objections to the labor involved in graduating distributions by means of this function. If greater detail is needed than is given in this table, then, by perfectly straightforward computation and the use of tables of the probability integral, Equations (88) may be utilized to fill in this detail. Tables of the probability integral have been published frequently and distributed widely; Mr. Foster's statement that these tables are "not always available to the practicing engineer" and that "even if available, might easily lead the average engineer into difficulties" is, therefore, quite disturbing. The answer to this objection is probably that the "average engineer" should not attempt, with his small equipment, to analyze a highly specialized and difficult problem. Undoubtedly, it is true that some kind of an answer may always be found easily to any statistical problem, but it is in the interest of "practical purposes" that this answer should be questioned and its reliability tested. It is unfortunate that statistical analysis does not offer many short cuts, particularly since a wide variety of important problems yield to no other kind of analysis.

Both Professors Goodrich and Mavis disagree with the writer's statements regarding the undesirability of graphical methods of analysis. These statements the writer intends, of course, to apply to the graphical analysis of statistical problems specifically, because he is well aware of the value of graphical analysis in general. Without entering into elaborate arguments, his objections to the graphical method may be stated briefly, as follows: If an n-parameter curve is to be fitted to a set of data, then exactly n independent statements must be used to determine these parameters. If a statistical series is capable of furnishing four independent, significant characteristics (for instance, the mean, standard deviation, skewness, and kurtosis, or, as the writer prefers for small samples, the mean, standard deviation, and the two end points of the range of variation), then these statements are sufficient to determine reliably a four-parameter curve; more parameters may be determined by making use of moments higher than the fourth, or by the method of least squares; but if the significant characteristics of the distribution are only four, the added work is meaningless; that is, there is a definite point beyond which the flexibility of a curve is undesirable. Now, a free-hand curve is a many-parameter curve (theoretically the number of parameters is infinite), and there seems to be no way of making the order of its flexibility agree with the flexibility that the statistics can significantly stand.

Professor Goodrich's method undoubtedly gives closer fits in a great many cases than are obtained by the function the writer proposes (the partly bounded function is obviously not flexible enough to represent the variations in the samples given as illustrations), but this added flexibility is scarcely a desirable feature when dealing with inadequate samples.

In functional analysis (as distinct from statistical analysis) the probable errors of the constants of a curve fitted to a set of data may be computed by the methods developed from the theory of least squares because of the reasonable assumption (in most cases, at any rate) that the variations in the observations from the true functional relation follow a symmetrical law closely represented by the Gaussian normal. In fitting a curve to a statistical series, however, the errors arise in an entirely different manner; they are errors in the characteristics of the distribution function itself. These errors are seldom small quantities of the first order, and so one is scarcely justified in computing the probable errors of the constants of the curve from them, even though by means of them the difficulties of correlation emphasized by Messrs. Fisher and Kempert are obviated (since statistical characteristics are mutually independent). In 1902, Pearson gave[58] the probable errors of statistical characteristics. The writer uses these values, reducing the order

of the moments to any desired degree by a suitable recursion formula (Equations (22), for instance), and computes two curves, one with the errors added to the characteristics as computed from the sample and the other with the errors subtracted. This gives a range within which the curve characteristic of the population has something better than an even chance of lying. The important and difficult subject of errors of sampling has not yet received adequate attention from engineers.

Professor Mavis raises an important question with regard to the representation of finite and discrete variates by means of a smooth frequency curve. Few phenomena in applied mathematics have been so misunderstood as the nature of a frequency function. A smooth curve does not imply that the variate is continuous or that the variations are infinite in number, although in so-called derivations, still abundant in treatises, such notions appear implicitly and explicitly. The fact is that the ordinates of a frequency curve do not give frequencies. The frequencies are always given by the area included between the curve, the class interval, and the two class limits. These frequencies, therefore, are always discrete. It is true that the mid-ordinate of a class (when the class interval is taken as 1) is usually numerically close to the frequency of the class, so that this ordinate is often taken as the frequency; but the frequency is always given by an area. When the variate is continuous and the number of variations infinite, one may only estimate the frequency of the values of the variate within the class limits; in the continuous case, the frequency of a single value is always zero.

In calling the totally bounded function the most general homograde function, the writer is stating a definition and, consequently, cannot be falling into a logical error. He is, in effect, formulating a physical law. This formulation is empirical, and it will take experience and not mathematics to prove it right or wrong. It is well known that the small errors of precise measurements are distributed, to a high order of approximation, according to the normal law. The mean and the standard deviation are the two characteristics necessary to determine such distributions and, for them, there are no other independent characteristics. When the causes producing variations are not infinite in number and are not mutually independent, then these two characteristics do not suffice and two others must be introduced. The writer then considers the four-parameter generalization of the Gaussian normal the most general homograde distribution, more complicated distributions being merely superpositions of this type.

Thiele's observations, as mentioned by Mr. Fisher, regarding the "pseudo-normal" variate, $t = h(x)$, are not discoveries in the theory of statistics, but merely special cases of theorems from the general theory of curves. Any two curves, provided they satisfy certain conditions of uniformity, may always be transformed into one another by suitable transformations. A theory of "pseudo-normal" variates, therefore, is quite as general as the integral equation or the Gram-Charlier formulations. The great advantage of such an observation (and the writer has availed himself of it) is that tables of the probability integral may be used with the more general function.

The writer was in error in attributing Equation (10) to Mr. Fisher, and he did not notice, until it was too late to acknowledge it, that the partly bounded function is exactly equivalent to his generic function; he was confused, on reading Mr. Fisher's treatise, by the discussion of the "mathematical zero." The writer objects to the use of it as a generic function, at least when dealing with small samples, for reasons already stated.

The work of the Danish statisticians is known to the writer only through Mr. Fisher's work and he was not aware of Thiele's generalization, Equation (68). Thiele. however, does not show how to compute the constants of this curve in terms of the statistical characteristics; in this respect, at any rate, the writer has shown some originality. The awkwardness in the writer's presentation, referred to by Mr. Fisher, was to a large extent, unavoidable. In the first place, the writer has definite limitations of expression and knowledge; in the second place, the "obvious" detail in the analysis and the choice of mathematical procedure was deemed desirable in presenting a paper of this sort to engineers instead of mathematicians. In defense of the analysis of Article 6, Section II, which Mr. Fisher considers superfluous, the writer should like to state that the approach of the logarithmic function to the limit, $\frac{x}{\sigma}$, as the skewness vanishes, is by no means self-evident (although it may be well known to mathematicians). If the transformation chosen had been the simple "pseudo-normal" variate, $t = h(x) = ax^3$, then for no value of the parameter, a, would the resulting curve have reduced to the normal, Thiele's theory notwithstanding. Thiele's theory leads to the Gaussian for the vanishing of the higher parameters simply because of the form he chose for his semi-invariants. Another form would have led to a different fundamental function. The theory of integral equations teaches one that the normal functions of a problem depend on the kernel of the equation and not on whether the equation arises in the theory of statistics, or in mechanics, or in some other manner. Thus, it happens that Equations (75) and (78) are mathematically equivalent. Both represent any function, whether frequency or not, which is continuous and vanishes, together with its first derivative, at infinity in both directions.

Mr. Fisher is inaccurate in inferring that the writer's statements regarding the generality of these two equations implies that a Fourier series is inferior to a Taylor series. What they do imply is that both the Fourier and the Taylor series are mathematical devices which sometimes offer a comparatively easy means of solving a difficult problem — more often than not the solution thus obtained will be purely formal and of little practical value.

Elsewhere,[59] the writer has proposed a method for determining the maximum and minimum floods from a record of yearly floods. In this method the constants have been determined only for use with yearly floods and as it stands, it is not applicable to the example furnished by Mr. Hall. The form of the equations has been suggested by theory—physical and statistical—

---

[59] Report to the Mississippi Valley Committee, July, 1935.

but their use in their present state can be justified only by the consistency of the results obtained by means of them in the problems attempted by the writer. The following quantities are used: g = maximum upper deviation from the mean, where the mean is taken = 1; b = maximum lower deviation from mean; g_o = maximum observed upper deviation; b_o = maximum observed lower deviation; A = drainage area, in square miles; M = mean flood, in feet per second; and, N = number of years in record. From these the following two quantities are computed: $\frac{0.4\, g_o}{b_o}$ = storm index; and, $\sqrt[3]{\frac{A}{M}}$ = flood index.

Using logarithms to the base 10, compute:

$$x = 6.7 - \left(0.5 \log N + 1.5 \log A + \frac{0.4\, g_o}{b_o}\right) + \sqrt[3]{\frac{A}{M}} \quad \ldots\ldots (89)$$

from which the maximum upper deviation is computed by the formula:

$$g = g_o\,(1 + 10^x)\left(0.7\sqrt[3]{\frac{A}{M}} + 0.8\right) \quad \ldots\ldots\ldots\ldots (90)$$

In cubic feet per second, the maximum flood will be given by $M(1 + g)$.

For the maximum lower deviation the same two equations are used, except that where g_o appears, $\frac{2\, b_o}{(1 - b_o)}$ is substituted, and where b_o appears, $\frac{g_o}{(2 + g_o)}$ is substituted. Equation (90), then, gives a quantity, b', say, from which,

$$b = \frac{b'}{(2 + b')} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (91)$$

and the minimum flood is given in cubic feet per second by $M(1 - b)$.

The late Allen Hazen, M. Am. Soc. C. E., presented[60] an example that shows the effect of the large flood of 1913 on the yearly flood record of the Hudson River, at Mechanicsville, N. Y. If the 23-yr record[61] ending in 1912 is taken, then $N = 23$; $A = 4\,500$; $M = 41\,700$; $g = 0.43$; and, $b = 0.37$. Substituting these values in Equations (89) and (90), it is found that $g = 2.225$, from which $3.225 \times 41\,700 = 134\,600$ cu ft per sec for the maximum flood. If the 34-yr record[62] ending in 1923 is taken, then the quantities are: $N = 34$; $A = 4\,500$; $M = 44\,000$; $g = 1.56$; and $b = 0.41$; and thus $g = 2.285$ and the maximum flood is 144 600 cu ft per sec. Although the two graphs show quite different characteristics, the values computed from them for the maximum flood are seen to be fairly close. Likewise, from two records of the Arkansas River,[63] the maximum flood is computed to be close to 50 000 cu ft per sec. These two rivers have equal drainage areas, but quite different flood and storm indices. (The storm index as herein given is a very variable quantity and characteristic of the particular record only.)

[62] *Loc. cit.*, Fig. 15, p. 78.

[63] *Loc. cit.*, Fig. 29, p. 89, and Fig. 34, p. 84.

To use Table 22: (*a*) Find the mean, M, and the standard deviation, σ; (*b*) estimate b and g; and, (*c*) compute $\lambda = \frac{b}{\sigma}$ and $\theta = \frac{g}{b}$. Table 22 gives values of t corresponding to percentages of time for various values of λ and θ. First-difference interpolations will usually be necessary. Then, compute (*d*) $X = (\sigma t + M)$, which is plotted against the corresponding %-of-time.

Table 2 of the paper simply gives the particular case in which g is infinite. It may be stated explicitly that the tables are computed for $\sigma = 1$, but that, because of the homogeneity of the function, any standard deviation is taken into account in Step (*d*) of the foregoing instructions. When b is greater than g, the function is left skewed. Because of the symmetry in b and g of the logarithmic linear fractional transformation, the same tables may be used in that case by merely interchanging b and g.

For instance, taking the 34-yr record for the Hudson River, $g = 2.285$; and, $b = 0.525$. Hazen gave the value, 0.37, for the standard deviation, CV, in this case, and if an attempt is made to fit the curve with this value, it is found to be too far off the main body of the statistics—the 1913 flood pulls it up considerably. Even this poor fit gives to this flood a probability of being equalled or exceeded but once in about 1 000 yr, so that since this flood contributes vastly more than its share to the standard deviation, one may conclude that a better estimate of this value may be made by taking only the forty-two values that exclude it. In this way the standard deviation is found to be 0.26. (For all these computations the flood magnitudes have been scaled from the diagrams previously cited,[60] and a 10-in. slide-rule has been used.)

To compute the standard error in the standard deviation, first calculate,

$$\beta = \left(\frac{\sigma^3}{b^3} + \frac{3\,\sigma}{b}\right)\left(\frac{g - b}{g + b}\right) \qquad \text{(92)}$$

from which the required error is given by,

$$\epsilon\,(\sigma) = \tfrac{1}{2}\,\sigma\,\sqrt{\frac{3\,\beta^2 + 4}{2\,N}} \qquad \text{(93)}$$

Equation (93) is obtained from Pearson's relations for the error in the moments in connection with the recursion formulas, Equations (22), and modified so as to be applicable to the general function. These expressions are not exact, but they give values for the error comparable to those obtained by the cumbersome exact formulas. Using the foregoing values for the Hudson River, the error is found to be 0.04. The curve for $\sigma = 0.26 + 0.04 = 0.3$ will be computed. With this value, $\lambda = 1.75$ and $\theta = 4.36$. From Table 22(*d*) by interpolating between the columns for $\lambda = 1.5$ and $\lambda = 2.0$, Column (1) of Table 23 is obtained. Column (2) is obtained from

Table 22(e) by the same interpolation. Then, adding to Column (1) Table 23, 0.36 times the differences between the entries in Columns (1) and (2), Column (3) is obtained. Column (4) = 0.3 × Column (3) + 1, and is plotted against the %-of-time values given in Column (5), Table 23. The curve is shown in Fig. 9. For $\sigma = 0.26$ the curve is slightly flatter and crosses the plotted curve at about the mean.

ANALYSIS OF CONTINUOUS STRUCTURES BY TRAVERSING THE ELASTIC CURVES

By Ralph W. Stewart,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Garrett B. Drummond, Austin H. Reeves, E. G. Paulet, Adolphus Mitchell, David M. Wilson, W. H. Kirkbride, R. B. Ketchum, A. Floris, Ivan M. Nelidov, Fang-Yin Tsai, and Ralph W. Stewart.

Synopsis

A method of analyzing the moments in the members of continuous frames by a geometrical solution of the alignment of their elastic curves, is presented in this paper. Memorized or copied slope-deflection equations are not used, and a series of rules for the signs of moments, rotations, and deflections are unnecessary.

Principles Involved

Three basic principles are involved[2]:

(1) The angular change of the tangents at any two points on the elastic curve of a flexed beam is equal to the area between the two corresponding sections on the $\frac{M}{EI}$ - diagram.

(2) The curvature mentioned in Principle (1) may be represented as an angle which, in radians, is numerically equal to the corresponding $\frac{M}{EI}$ - area. This angle is platted opposite the center of gravity of the part of the $\frac{M}{EI}$ - diagram under consideration.

(3) For any unit of the $\frac{M}{EI}$ - diagram a triangular traverse of the cor-

---

Note.—Published in October, 1934, *Proceedings*.

[1] Engr. of Structural Design, City of Los Angeles, Los Angeles, Calif.

[2] *Civil Engineering*, February, 1934, p. 88.

responding unit of the elastic curve can be constructed. This triangle is composed of the tangents and the chord of the elastic curve. The angle between the tangents is given by Principle (2). Each angle between a tangent and the chord is directly proportional to the opposite side. This is because in beam flexure the angles are so small that they may be taken as equal to their sines.

The traversing triangle thus constructed can be solved if one angle and one side are known.

Applications to Structures

In the cantilever beam (Fig. 1), the traversing triangle is *ABC*. The angle, Δ, is equal to the area of the moment diagram $= \dfrac{M\,l}{2\,EI}$. Angle $CAB = \dfrac{2}{3}\,\Delta$ and Angle $CBA = \dfrac{1}{3}\,\Delta$. The deflection equals:

$$d = \Delta \times \frac{2}{3}\,l = \frac{M\,l^2}{3\,EI} = \frac{P\,l^3}{3\,EI} \quad\ldots\ldots\ldots\ldots\ldots\ (1)$$

As an alternate solution the full length of the beam may be multiplied by $\dfrac{2}{3}\,\Delta$ as shown by Fig. 1(*b*).

Fig. 2 represents a span of a continuous beam in flexure which involves end slopes, end moments, and end translation as indicated. In dividing the moment diagram into units it will simplify the solution to add the dotted line, *AB*, and treat the moment diagram as being composed of two triangles, *ABD* and *BAC*, each running the full length of the beam. The triangle, *ABE*, is a positive addition to the real M_1-triangle and a negative addition to the real M_2-triangle and, therefore, cancels its effect on the final deflection and end slope of the span.

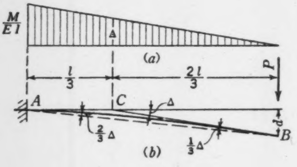

FIG. 1.

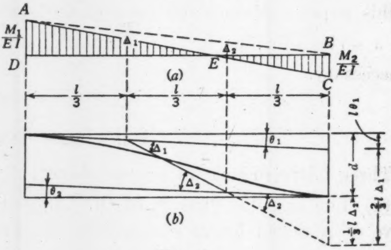

FIG. 2.

From the center of gravity of Triangle *ABD* drop a vertical to the tangent through the left end of the elastic curve and lay off Δ_1 equal to the area of Triangle *ABD*. From the center of gravity of Triangle *BAC* drop a vertical to the lower leg of Δ_1 and lay off Δ_2 equal to Area *BAC*. Produce the upper leg of Δ_2 to the right end of the beam and draw the horizontal line indicating the end slope, θ_2.

From Fig. 2(*b*), it is now possible to read the following equations:

$$\theta_1 + \Delta_1 = \theta_2 + \Delta_2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

and,

$$d = l\,\theta_1 + \frac{2}{3}\,\Delta_1 l - \frac{1}{3}\,\Delta_2 l \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Solving:

$$-\,\Delta_1 = 2\,\theta_1 + \theta_2 - \frac{3\,d}{l} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Equating Δ_1 to its value, $\frac{M_1 l}{2\,EI}$, and solving for M_1:

$$-\,M_1 = 2\,E\,\frac{I}{l}\left(2\,\theta_1 + \theta_2 - 3\,\frac{d}{l}\right) \quad \ldots\ldots\ldots\ldots (5)$$

Equation (5) will be recognized as a standard slope-deflection equation. It will not be used in subsequent solutions, but is introduced to illustrate the utility of the traverse method in deriving it. The line, $\Delta_1\,\Delta_2$ (Fig. 2(*b*)), is not tangent to the elastic curve, but crosses it at an angle, due to the addition of Triangle *ABE* to the moment diagram. If the true, shaded, moment triangles were used for locating and evaluating the Δ's, the line, $\Delta_1\,\Delta_2$, would be tangent to the elastic curve at its point of contraflexure, but the distances from the ends of the beam to the Δ's would be inconvenient and would make the solution complicated.

FIG. 4.

In order to illustrate the solution of the moments in a continuous frame by the elastic curve traverse without encumbering the problem with avoidable complications, reference is made to Fig. 3. This diagram shows a symmetrical frame with fixed base columns carrying a concentrated load at the center. The columns and the beams have equal lengths and cross-sections.

The true moment triangles in the beam are shown by the shaded areas. In order to simplify the traverse, the unshaded trapezoidal area between the closing line and the top of the diagram is added to the shaded center

$\frac{M}{EI}$ - triangle, thereby forming a "simple-beam" $\frac{M}{EI}$ - triangle, the middle ordinate of which is $\frac{P\,l}{4\,EI}$. The combined area of the shaded end $\frac{M}{EI}$-triangles is also increased by the area of this same trapezoid. The resultant curvature in the beam will then be the same as if the true shaded moments only were used, and the diagram may be treated as composed of three $\frac{M}{EI}$ - triangles, comprising the end $\frac{M}{EI}$ - triangles the base of which runs the full length of the beam, and the simple-beam $\frac{M}{EI}$ - triangle the height and area of which are $\frac{P\,l}{4\,EI}$ and $\frac{P\,l^2}{8\,EI}$, respectively. This device is used and discussed in treatises on "slope deflection", to which reference may be made, if further study is desired.[3]

The deflection curves may now be traversed. Each angle in the traverse is equal to the area of its corresponding $\frac{M}{EI}$ - triangle. Beginning at the bottom of the left column the traverse is as follows (the signs for the angles needing no discussion as they are the same as would be used for azimuth in a land survey):

$$-\Delta_1 + \Delta_2 + 90^\circ + \Delta_3 - \frac{P\,l^2}{8\,EI} + \Delta_4 + 90^\circ + \Delta_5 - \Delta_6 = 180^\circ \quad (6)$$

in which, Δ_2, Δ_3, Δ_4, and Δ_5 are all equal since their values of $\frac{M}{EI}$ and the lengths of members are equal. There being no side-sway the triangles along the upper two-thirds of the columns are isosceles; consequently, $\Delta_2 = 2\,\Delta_1$ and $\Delta_5 = 2\,\Delta_6$. Therefore, Equation (6) reduces to $3\,\Delta_2 = \frac{P\,l^2}{8\,EI}$, or,

$$\Delta_2 = \frac{P\,l^2}{24\,EI} \quad (7)$$

Substituting $\frac{M_2\,l}{2\,EI}$ for Δ_2, the corner moments are $\frac{P\,l}{12}$. The moments at the bases of the columns are $\frac{P\,l}{24}$, and the center moment is $\frac{P\,l}{4} - \frac{P\,l}{12} = \frac{P\,l}{6}$. As shown by Equation (6) the signs of the corner moments are opposite the signs of the center moment and column base moments.

The joint rotations do not enter into the solution, but the equations are formed from the curvature units in the members. This distinguishes the traverse method from the slope-deflection method in which standard equations involving joint rotations are applied.

---

[3] *Bulletin 108,* Eng. Experiment Station, Univ. of Illinois, Urbana, Ill.; Concrete Engineers Handbook, by Hool and Johnson; etc.

Fig. 4 illustrates the application of the traverse method to an unsymmetrical frame having fixed base columns and subjected to a horizontal force, P. The material in the frame is assumed to be uniform and E may be eliminated from the equations.

From the $\frac{M}{I}$-diagram, $\Delta_2 = \frac{M_2\,h}{2\,I_1}$ and $\Delta_3 = \frac{M_3\,l}{2\,I_3}$; but, since $M_2 = M_3$, $\Delta_2 = \frac{I_3\,h}{I_1\,l}\,\Delta_3 = k_1\,\Delta_3$; similarly, $\Delta_5 = k_2\,\Delta_4$. The angles and courses in the deflected frame constitute a traverse for which the following equations may be written: $\Delta_1 - \Delta_2 + 90° - \Delta_3 + \Delta_4 + 90° + \Delta_5 - \Delta_6 = 180°$; or,

$$\Delta_1 - \Delta_2 - \Delta_3 + \Delta_4 + \Delta_5 - \Delta_6 = 0 \ldots\ldots\ldots\ldots\ldots (8)$$

The vertical deflection of the right end of the beam with reference to the left end is zero; or,

$$l\,\theta - \frac{2}{3}\,l\,\Delta_3 + \frac{1}{3}\,l\,\Delta_4 = 0 \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

Since, $\theta = \Delta_1 - \Delta_2$, Equation (9) becomes:

$$\Delta_1 - \Delta_2 - \frac{2}{3}\,\Delta_3 + \frac{1}{3}\,\Delta_4 = 0 \ldots\ldots\ldots\ldots\ldots (10)$$

Similarly,

$$\Delta_6 - \Delta_5 - \frac{2}{3}\,\Delta_4 + \frac{1}{3}\,\Delta_3 = 0 \ldots\ldots\ldots\ldots\ldots (11)$$

Since the lateral deflections of the column tops are equal,

$$\frac{2}{3}\,\Delta_1\,h - \frac{1}{3}\,\Delta_2\,h = \frac{2}{3}\,\Delta_6\,h - \frac{1}{3}\,\Delta_5\,h$$

from which,

$$2\,\Delta_1 - \Delta_2 = 2\,\Delta_6 - \Delta_5 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

Since the sum of all column moments $= Ph$,

$$M_1 + M_2 + M_5 + M_6 = Ph$$

from which,

$$\Delta_1\,I_1 + \Delta_2\,I_1 + \Delta_5\,I_2 + \Delta_6\,I_2 = \frac{P\,h^2}{2} \ldots\ldots\ldots\ldots\ldots (13)$$

Substituting $\frac{\Delta_2}{k_1}$ for Δ_3 and $\frac{\Delta_5}{k_2}$ for Δ_4, in Equations (8) to (12), solving for Δ_2, and then substituting for Δ_2 its value, $\frac{M_2\,h}{2\,I_1}$:

$$M_2 = \frac{P\,h}{2} \times \frac{1}{1 + \frac{1}{3\,k_1} - \frac{1}{6\,k_2} + q\left(1 + \frac{1}{3\,k_2} - \frac{1}{6\,k_1}\right)} \ldots\ldots (14)$$

in which, $q = \dfrac{2 + k_1}{2 + k_2}$. If $I_1 = I_2$, then $k_1 = k_2$ and $q = 1$, and Equation (14) reduces to a much simpler form.

In practical problems of this type the work is greatly simplified, as the numerical values of constants, such as k_1, k_2, I_1, I_2, and $\dfrac{P\,h^2}{2}$, are inserted in the initial equations.

The use of the traverse method for the variable moment of inertia and a settled support is illustrated by Fig. 5, which represents a beam fixed at

one end and with a support which has settled 1 in. at the other. The moment of inertia and the modulus of elasticity may both be variable. From Maxwell's theorem, the final distortion of the beam from the combined action of the external forces may be treated as the sum of the distortions, due to each force acting separately.

With the force, P, acting alone, the deflection of the right end of the beam would be $a\,\Delta_P$ (Fig. 5(c)), in which, Δ_P is the area of the $\dfrac{M}{EI}$ - diagram for the beam considered as a cantilever supporting the load, P, and a is the distance from the right end to the center of gravity of this $\dfrac{M}{EI}$ - area. Assume a trial reaction, R, compute the appurtenant $\dfrac{M}{EI}$ - diagram due to the cantilever uplift of the trial reaction acting alone, and locate its center of gravity, distant from the right end, as shown below the horizontal line in Fig. 5(*b*). The Trial Δ_R and its uplift at the end of the beam ($= b \times$ Trial Δ_R) can now be added to the traverse as shown in Fig. 5(*c*). The true value of R necessary to raise the right end of the beam to its settled position is now given by the proportion, $\dfrac{\text{True } R}{\text{Trial } R} = \dfrac{b\,\Delta_R - 1 \text{ in..}}{b \times \text{Trial } \Delta_R}$. With the value of R determined, the moments may be computed by statics.

TRAVERSE METHOD A SUBSTITUTE FOR THEOREM OF THREE MOMENTS

Fig. 6 represents a series of continuous equal spans with a moment at the right end. The traverse method furnishes a quick and easy solution for all the moments and all the slopes of the elastic curve over the supports by the following construction: Beginning at the left end of Fig. 6(*c*) draw a traverse triangle for the flexure of the elastic curve of the left span. A low altitude for this triangle should be used, but no particular scale for the angles is necessary. Produce the long leg of the diagram to Point 2

over the second support and produce the short leg to the point marked **1** at the one-third span length of the second span. Draw Line 2-1-4-8. Through Point 4 draw Line 4-4 passing through the third support. Draw Line 8-4-15, etc. The result is a series of "pennant" diagrams. Each angle marked Δ is a measure of the moment at the support to its right. The position of Δ above or below the horizontal through the supports shows whether the moment is positive or negative. All angles in Fig. 6(*c*) can be evaluated quickly by simple summation and by determining the products of angles and horizontal distances. For example, to find Δ_2,

$$\frac{2}{3}(l) + 1\left(\frac{2}{3}l\right) - \Delta_2\left(\frac{1}{3}l\right) = 0$$

Therefore, $\Delta_2 = 4$.

Each line through a support is tangent to the elastic curve. Its angle with the horizontal is the measure of the slope of the elastic curve at the support and is obtained by summation. For example, the relative slope over the third support is, $\frac{2}{3} + 1 - 4 = -\frac{7}{3}$. In Fig. 6(*c*) the value of each angle is shown at the angle point. Signs are omitted as unnecessary because the picture of the flexure discloses the direction of moments. Below Fig. 6(*c*) are shown the relative magnitude of the moments at the supports, the relative magnitude of the end slopes, and the ratio of each moment to the preceding moment. Fig. 6(*d*) shows the traverse for the same system with the left end fixed. Note that the numerical series for moments in Fig. 6(*c*) is the same as that for end slopes in Fig. 6(*d*), and *vice versa.* The moment at any support is now known in terms of the moment at the right end. For example, in Fig. 6(*c*), if the right end moment is 3 000, the moment at the second support will be $\frac{1}{209} \times 3\,000$.

If the number of spans is infinite the ratio of each moment to the preceding moment will be 3.73205. The difference between this ratio and the ratios at the fourth support in Fig. 6 is negligible in practical design.

The application of the traverse method to unequal span lengths and loaded spans can be demonstrated by a problem solved previously[4] by L. H. Nishkian and D. B. Steinman, Members, Am. Soc. C. E. For the present purpose, Fig. 7 need not be, and is not, drawn to scale. Free-hand sketching is recommended in practical work. It is known that negative moments will occur over the supports. Sketch in the four moment triangles, Δ_1, Δ_2, Δ_3, and Δ_4, illustrating the existence of such moments. Draw simple moment diagrams for the loading of each span using either the upper lines of the negative moment triangles for bases, as shown, or, if desired, using the horizontal line through the supports as a base. It will make no difference in the computations which is used.

Draw verticals through the centers of gravity of the negative moment triangles (at the third points of the beam) and through the centers of gravity of the simple moment diagrams, which, in this case, are at the centers of the beam. Draw the T-lines (transposition lines[5]) as shown.

---

FIG. 7.

Draw Line $\Delta_1 \cdot \Delta_2$ passing through the support and extended to the vertical through the one-third length of the second span. Draw the line from $\Delta_1 + \Delta_2$ through Δ_2 to the vertical through the center of the span at A_2. Draw Line A_2 Δ_3 to pass over the third support, intersecting the T-line at $\Delta_3 + \Delta_4$. Continue this line sequence to the right end of the beam. Fig. 7(c) can now be solved for the values of the Δ-angles by giving the A-angles values that equal the respective areas of the simple moment diagrams and observing that $\frac{\Delta_1}{\Delta_2} = \frac{l_1}{l_2}$ and $\frac{\Delta_4}{\Delta_3} = \frac{l_3}{l_2}$. Solving for these Δ-angles and reducing them to their corresponding moments, the moment over the second support is found to be 97 166 ft-lb and the moment over the third support, 92 666 ft-lb. The T-lines are on the centers of gravity of the combined abutting negative moment triangles and this is what accounts for their mechanical significance.

The traverse method can be used for spans of variable moment of inertia by the use of trial end moments to locate the Δ-points and to obtain the relative $\frac{M}{EI}$- areas for equal end moments. Tables introduced[6] by Walter Ruppel, Assoc. M. Am. Soc. C. E., will facilitate this work for the cases to which the tables apply. Tables that give $\frac{M}{EI}$ - areas for simple moments are unknown to the writer. Settlement of supports and side-sway can be incorporated in the geometry of a traverse.

[5] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 8.

[6] *Loc. cit.*, pp. 167–187.

For the design of a member in a building of many stories and many bays, traverses in the form of Fig. 6 can be distributed vertically and horizontally to the columns and girders at the ends of the member. If the columns are flexible as compared with the girders they may be assumed to be fixed at floors above and below the joint in question, while the girders may be assumed to have a ratio of moment at the joint in question to moment at the joint one panel length distant, based on the factors indicated by Fig. 6 modified by an allowance for the joint stiffening effect of the columns. It will be found that a member can be designed quite satisfactorily by using moderately accurate judgment as to these moment ratios. If precision is desired and time is available the traverses may be extended two panel lengths, or more, from the member under consideration.

For the derivation of the basic formula for moments in single-span beams, fixed at one or at both ends, the traverse method offers alternate solutions which require a small fraction of the effort involved in the method of successive integrations found in textbooks on mechanics.

CONCLUSIONS

The analysis of continuous structures by traversing their elastic curves offers solutions that are easily understood and for which diagrams that clearly illustrate the problems can be easily drawn. The key constants for the analysis are simple $\frac{M}{EI}$ - and cantilever $\frac{M}{EI}$ - diagrams the construction of which is taught in the first lessons on beam stresses.

The method relieves the analyst from remembering or holding for reference the various forms of the three-moment equations or the slope-deflection equations. It requires no more analytical effort or labor of computation than these or other previously used methods.

DISCUSSION

GARRETT B. DRUMMOND,[7] ESQ. (by letter).—The paper by Mr. Stewart is timely if for no other reason than that it emphasizes again what is the fundamental theory of indeterminate structures—the fact of continuity.

It is important to consider the limitations of the method as presented. The theory of continuity is based upon certain accepted assumptions: (1) It is assumed that the neutral axes of all members at a joint meet in a point; (2) distortions due to shear and direct thrust are negligible; (3) the relative rotation of the two ends of a member, for short lengths of the axis, is proportional to $\frac{l}{I}$ for the respective sections; and (4) the intensity and duration of the loading do not affect the elastic properties of the materials, thus permitting the assumption that for short lengths of beams the differential rotation of the two ends is directly proportional to the bending moment in the length considered.

These assumptions cause this method of analysis to be applicable in the strictest sense only to those materials which follow Hooke's law, and for steel only within the elastic limit. In structures of reinforced concrete or timber, Assumption (4) is not applicable since the ratio of stress intensity to deformation varies with both the intensity and the duration of stress. Assumption (3) does not apply to reinforced concrete.

However, it is probable that the assumption of a constant value of I in reinforced concrete beams will result in errors not exceeding 5 per cent. Such an error will not seriously affect the analysis of a reinforced concrete beam, although such limitations should be recognized.

For the determination of slopes and deflections, the writer finds it more convenient to utilize the method of stress areas. In this method, which obviates the assumption of the beam formula, the load is the area under the curve of fiber stress in the outer fibers, divided by $E\ c$, assuming $E\ c$ to be constant. The angular change of the tangents at any two points on the elastic curve is equal to the area between the two corresponding sections on the $\frac{f}{E\ c}$ diagram. The deflection at any point is equal to moment about that point, considering the beam to be loaded with the $\frac{f}{E\ c}$ diagram.

The method of stress areas is convenient when the fiber stress is known, and the slope and deflection are desired; or when the slope or deflection is known and the fiber stress is desired.

Fig. 8 represents a simply supported beam of constant cross-section, with a concentrated load at the center. The resulting curve of fiber stress will be as shown. The slope at the supports becomes $\frac{1}{4}\left(\frac{f\ l}{E\ c}\right)$, the same as the end

---

[7] Asst. Prof. of Math., Oklahoma Agrl. and Mech. Coll., Stillwater, Okla.

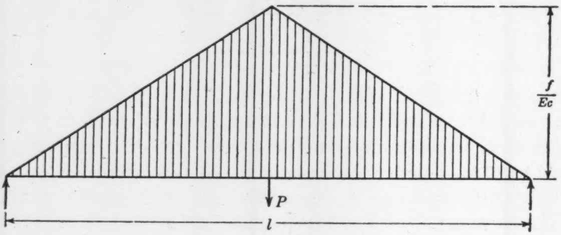

FIG. 8.

shear with $\frac{f}{E\,c}$ as a load. The deflection at the center is equal to the moment of this load at the center, or $\left(\frac{1}{12}\right)\left(\frac{f\,l^2}{E\,c}\right)$.

AUSTIN H. REEVES,[8] ASSOC. M. AM. SOC. C. E. (by letter).—A particularly valuable feature of the method described in this paper is that it provides a complete picture of the action of any loaded structure, no matter how complicated. However, some of the problems can be solved more speedily by other methods. For example, the writer solved the problem shown in Fig. 3 within 2 min, and the one shown in Fig. 4 within 5 min, by the conjugate point method.[9]

A check by the method presented[10] by Hardy Cross, M. Am. Soc. C. E., was made on both problems shown in Fig. 6 and also on the one shown in Fig. 7, and the results given by the author were found to be exact. The writer is in agreement with the "Conclusions."

This paper is a noteworthy contribution to the knowledge of rigid frame design.

E. G. PAULET,[11] JUN. AM. SOC. C. E. (by letter).—A geometrical solution for the analysis of continuous frames is presented in this paper, which is termed the "traverse method." In the "Synopsis", the author states that "memorized or copied slope-deflection equations are not used, and a series of rules for the signs of moments, rotations, and deflections are unnecessary." Notwithstanding that the three basic principles stated by the author would have to be remembered by any one unfamiliar with the moment-area method, the first principle, being one of the moment-area method, is sufficient to derive the fundamental slope-deflection equations at any time. Furthermore, the moment-area method furnishes the end moments of fully restrained beams subject to any type of loading, should one not have these values immediately available for use in conjunction with the slope-deflection equations.

When the slope-deflection method first came to the attention of the writer (whose mind, to that time, had been rigidly imbued with the "work methods" expounded by Europeans), he experienced some confusion at first, due to the signs of moments, rotations, and deflections. The solution of a few simple examples of frames ended the confusion and, to this day, the writer considers the slope-deflection method as the most forceful, next to the "work methods", for the rigorous analysis of rigid frames.

[10] *Loc. cit.*, Vol. 96 (1932), p. 1.
[11] Bridge Design Engr., State Highway Comm., Baton Rouge, La.

The author further states, following Equation (7):

> "As shown by Equation (6) the signs of the corner moments are opposite the signs of the center moment and column base moments.
>
> "The joint rotations do not enter into the solution, but the equations are formed from the curvature units in the members."

Equation (6) furnishes no criterion for the signs of the moments, because the signs of the Δ's depend upon the relative position of the bending moment diagrams, a position which can be chosen arbitrarily and erroneously. To visualize the elastic line of the deflected simple frame and write the Δ's with their proper signs in the equation-types, Equations (6) and (8), may be an easy task for the experienced engineer; however, a complex frame may present an untrue picture to him and leave him with a feeling of false assurance as to the correctness of the results.

In this respect, the traverse method has not as direct an approach to a problem as the slope-deflection method, the equations of which will furnish the correct signs and values of moments, rotations, and deflections, the signs being in accord with those adopted for deriving the equations.

The first and second principles of the traverse method will be helpful in finding the deflection of one end of a member, or series of members, relative to the other end, after the frame has been solved by the moment-distribution method.

Fig. 5 shows the application of the author's method to a beam of variable moment of inertia, and with a settled support. In the writer's opinion, problems of this kind are more directly solved by the moment-area method. Assuming that the correct arrangement of bending moment diagrams for a loaded continuous beam of uniform moment of inertia is established, the traverse method lends itself to a simple and rapid solution of such a problem.

In Fig. 6(*c*), the closing line of the "pennant" diagrams (Lines 2-1-4-8, 8-4-15-30, etc.) of the unloaded spans intersects the base line at a point of zero moment, through which (after the moments over the supports of the loaded span have been computed by the traverse method and platted to any convenient scale), the closing line of the bending moment diagrams for the unloaded spans may be drawn directly, and the moment at any point read to that scale.

From Fig. 6(*c*), it is noted with interest that the series for the relative moments and end slopes may also be found, beginning from the left end of the continuous beam, with the relations:

$$M_n = 2\,M_{n-1} + S_{n-1} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

and,

$$S_n = 3\,M_{n-1} + 2\,S_{n-1} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

in which, M_n = relative moments at the support under consideration; S_n = relative end slopes at that support; M_{n-1} and S_{n-1} = relative moments and end slopes, respectively, at the support preceding the one under consideration; and, at the first support, $M_1 = 0$, and $S_1 = 1$. For the case shown in Fig. 6(*d*), M reads S, and S reads M, in Equations (15) and (16).

ADOLPHUS MITCHELL,[12] JUN. AM. SOC. C. E. (by letter).—The method of analyzing continuous structures described in this paper, appears to hold no advantage over the slope-deflection method. On applying the two methods to multiple-story frames, one finds that whereas the slope-deflection method yields a simultaneous equation for each joint, the traverse method yields a simultaneous equation for each joint and member. The result is that an already large number of equations is doubled. Even in the simple problems solved by the author, the writer finds the slope-deflection method the easier.

Most designers are in the habit of assuming that the available foundation either offers no restraint or that it offers full restraint (fixed). As it is usually known that neither of these extremes is the case, the designer might wish to make some intermediate assumption. This can be done by comparing the geometry of the traverse for hinged and fixed conditions at End A of any member, AB. If f_{AB} is the percentage of fixation at End A:

$$\Delta_{BA} = \frac{2}{f}\ \Delta_{AB} \quad \text{(17)}$$

$$\theta_{BA} = \frac{1}{6}\ (4 - f)\ \Delta_{BA} \quad \text{(18)}$$

and,

$$\theta_{AB} = \frac{1}{3}\ (1 - f)\ \Delta_{BA} \quad \text{(19)}$$

For a hinged terminal at A, $f = 0$, and for a fixed terminal at A, $f = 1$.

The author has solved the problem illustrated by Fig. 3, assuming the column terminals to be fixed. Suppose the column terminals are 50% fixed and that it is desired to determine the corner moment. Applying Equations (17), (18), and (19), $\Delta_2 = 4\ \Delta_1$ and $\theta_{21} = \frac{7}{12}\ \Delta_2 = \theta_{34}$. Since M_2 must be equal to M_3, $\Delta_2 = \Delta_3$. Equating ordinates at the right end of Beam 34:

$$\frac{7}{12}\ \Delta_2\ l + \Delta_2 \left(\frac{2}{3}\ l\right) - \frac{P l^2}{8\,EI}\left(\frac{l}{2}\right) + \Delta_2\left(\frac{l}{3}\right) = 0$$

Solving for Δ_2,

$$\Delta_2 = \frac{3\,P l^2}{76\,EI} = \frac{M_2}{EI}\left(\frac{l}{2}\right)$$

and, hence,

$$M_2 = \frac{3}{38}\ Pl$$

---

[12] Structural Designer, State Highway Dept., Santa Fé, N. Mex.

This idea of fixation or restraint is the basis of the method introduced by T. F. Hickerson,[13] M. Am. Soc. C. E., which the writer prefers to that proposed in this paper. In most of the papers on this subject complete tables are given permitting application to members of variable moment of inertia with relative ease. The author presents no such tables and, thereby, his method suffers another handicap.

David M. Wilson,[14] Assoc. M. Am. Soc. C. E. (by letter).—Methods of analyzing continuous structures which are fundamental to an understanding of this important subject may be divided into two classes: (1) The Maxwell-Mohr Method of Work; and, (2) Special Methods, such as (*a*) Moment-Area Method; (*b*) Slope-Deflection Method; and (*c*) Moment-Distribution Method (Cross Method).

The Maxwell-Mohr method of work is based upon the principle of the conservation of energy. It is the most general method available and may be used in all cases.

The special methods in the foregoing classification apply only in the analysis of straight structural members in which bending is the cause of the primary deformations, those due to shear and direct stress being neglected. They may be developed from the method of work, or they may be derived independently. The special methods have extensive application in practice because they are convenient to use. However, one should remember that, in many cases, deformations due to shear and direct stress cannot be neglected safely and, therefore, the results obtained by special methods will not be significant.

The author has presented a method of analyzing the moments in the members of continuous frames which is based directly upon the principles of the moment-area method. It is of special interest because it pictures the approximate deformations of the structure being studied.

In general, every structural engineer has his own favorite schemes of analysis. The method proposed will undoubtedly be of value to the designer who uses the moment-area method in preference to all other methods, whereever it is applicable.

The moment-distribution method is the most workable of the special methods because the solution of simultaneous equations is not required. Furthermore, the unknown moments are determined directly without first solving for rotation angles as required by the slope-deflection method, or for delta angles as required by the author's method.

In many cases, a combination of the special methods is desirable. For example, the fixed-end moments used in moment distribution may be determined conveniently by the application of the principles of area moments. At the same time, a thorough knowledge of slope deflection is of great value in understanding the steps in moment distribution.

In order to compare the proposed method with the moment-distribution method, the writer solved the problem shown in Fig. 7 by each method. Referring to Fig. 7(*c*), the following equations from the author's method may be written since the vertical deflection of the beam at any support with reference to an adjacent support is zero:

---

[13] "Structural Frameworks", by T. F. Hickerson, Univ. of North Carolina Press, 1934.

[14] Associate Prof. of Civ. Eng., Univ. of Southern California, Los Angeles, Calif.

$$24\left(\frac{A_1}{2} - \tfrac{2}{3}\,\Delta_1\right) - 16\,\Delta_2 + 12\,A_2 - 8\,\Delta_3 = 0 \ldots\ldots\ldots\ldots (20)$$

and,

$$24\left(\frac{A_3}{2} - \tfrac{2}{3}\,\Delta_4\right) - 16\,\Delta_3 + 12\,A_2 - 8\,\Delta_2 = 0 \ldots\ldots\ldots\ldots (21)$$

Furthermore, from Fig. 7(*b*), $\Delta_1 = 7\,M_1$; $\Delta_2 = 12\,M_1$; $\Delta_3 = 12\,M_2$; and, $\Delta_4 = 9\,M_2$. Therefore, $\frac{\Delta_1}{\Delta_2} = \frac{7}{12}$, and $\frac{\Delta_4}{\Delta_3} = \frac{3}{4}$.

Eliminating Δ_1 from Equation (20) and Δ_4 from Equation (21); substituting for A_1, A_2, and A_3 their respective values; and solving the resulting equations: $\Delta_2 = 1\,164\,000$, and $\Delta_3 = 1\,112\,400$. Therefore, $M_1 = \frac{\Delta_2}{12} = 97\,000$ ft-lb, and $M_2 = \frac{\Delta_3}{12} = 92\,700$ ft-lb.

It is to be noted that the unknowns determined by solution of the simultaneous equations are not the desired moments. In a problem involving a large number of unknowns, the work necessary to solve the simultaneous equations would be prohibitive. On the other hand, the complete solution of an identical problem by the moment-distribution method is a relatively simple process,[15] in which the necessary work is approximately proportional to the number of unknowns.

There is no one simple method that can be applied in analyzing all continuous structures. Furthermore, no analysis is ever absolutely exact. Certain assumptions, based upon the elastic theory of structures, must be made before a problem can be solved by any of the available methods. The validity of these assumptions must be considered carefully in interpreting the results of the analysis. This requires sound engineering judgment at all times. The problem, therefore, is definitely one for the trained engineer with a comprehensive understanding of the behavior of structures under stress.

W. H. KIRKBRIDE,[16] M. AM. SOC. C. E. (by letter).—An interesting new method of stress analysis is introduced in this paper. The illustrations used by the author include portal frames the members of which meet at right angles.

Special methods, such as "slope deflection" and "end moment distribution," are also available for the analysis of such frames. The slope-deflection method, while in quite general use for rectangular frames, is not accepted as suitable for the analysis of frames having sloping tops. The end moment distribution method is also particularly adapted to rectangular frames. It does not permit of the derivation of a general formula in terms of symbols, which can be compiled into a handbook, and becomes less convenient when applied to frames the joints of which are deflected from their original position, due to the action of the loads.

---

[15] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

[16] Chf. Engr., S. P. Co., Pacific Lines and Subsidiary Lines, San Francisco, Calif.

It will be interesting to know whether the traverse method is applicable to frames with sloping tops.

R. B. KETCHUM,[17] M. AM. SOC. C. E. (by letter).—The various methods of analyzing continuous structures have involved the work of distortion, or the geometry of distortion, and Mr. Stewart's paper is a distinct contribution to the geometrical method of attack.

The paper seems to have possibilities of expansion in a wide range of problems and would be a valuable check in graphical methods of drawing elastic curves and studying complicated loading conditions that have many unknowns, for which "cut-and-try" methods are used. The writer would be interested to know whether the author has applied this method to frames with sloping tops.

A. FLORIS,[18] ESQ. (by letter).—The methods for the analysis of statically indeterminate structures can be grouped into two main categories: Those in which forces are used as the redundants and those in which moments are utilized for the same purpose. They are termed the "force" and "deformation" methods, respectively.

The author's analysis is pre-eminently a deformation method with the moments at the corners and over the supports as the redundants. By replacing the deformed structure by the traverse (that is, by a set of straight lines), its flexure can be more readily visualized. The intersections of these lines determine the angles corresponding to the bending moment areas of simple beams and cantilevers divided by the stiffness factor, $E\,I$. This interpretation of the elastic curve has the additional advantage that many of the aforementioned angles can be determined by inspection. The seemingly great number of unknown angles is thus reduced considerably, and the solution of complicated problems is rendered more simple. The merit of the present analysis is based on this fact. As a further development of the traverse method, Mohr's theorem pertaining to rotations and deflections of loaded beams is utilized.

The traverse method is theoretically interesting and practically valuable. It is hoped, therefore, that the method will be used by engineers engaged in the design of statically indeterminate structures.

IVAN M. NELIDOV,[19] ASSOC. M. AM. SOC. C. E. (by letter).—This is a method by which moments in a continuous structure can be found with the aid of a traverse, the deflection angles of which correspond to $\frac{1}{E\,I}$ times the moment areas of the moments involved.

---

[17] Dean, School of Mines and Eng., Univ. of Utah, Salt Lake City, Utah.

[18] Dipl.-Engr., Los Angeles, Calif.

[19] Senior Engr. of Hydr. Structure Design, State Dept. of Public Works, Sacramento, Calif.

The first consideration in analyzing a structure is the balance between the unknown factors and the available equations. If a structure consists of m members with j interior joints and s supports, the total number of unknowns is: $n = 5\ m$. The number of available equations is:

1.—m-equations of geometry of the type,

$$\Sigma\ (\theta + \Delta) = 0 \qquad (22)$$

2.—m-equations of geometry of the type,

$$\Sigma\ d = 0 \qquad (23)$$

3.—$\Sigma\ (x - 1)\ j$-conditions of rigidity in the joints, of the type,

$$\theta_k = \theta_{k+1} \qquad (24)$$

(in which, x is the number of members meeting at the joint).

4.—j-conditions of equilibrium in the joints, of the type,

$$\Sigma\ M_k = 0 \qquad (25)$$

5.—s-conditions at the supports, of the type,

$$\theta_s = a \qquad (26)$$

or,

$$M_s = b \qquad (27)$$

6.—A certain number of conditions of rotation at the joints, of the type,

$$\theta_k = c \qquad (28)$$

7.—A certain number of conditions of deflection at the joints, of the type,

$$d_k = d \qquad (29)$$

8.—A certain number of conditions resulting from the symmetry of load and the structure.

Conditions 1 to 8 reduce the original number of the unknowns, but since there are more conditions ordinarily than equations, the deficient number of equations should be supplied from the conditions of the equilibrium of the external and the internal forces.

As a simple illustration of the application of Mr. Stewart's method and of Conditions 1 to 8, the following example is proposed: Find the moments in the frame shown in Fig. 9, which is symmetrical about its center line and symmetrically loaded by a concentrated load at the apex. It will be seen that $m = 4$, $j = 3$, and $s = 2$. The total number of unknowns is $n = 5\ m = 20$, which is reduced, due to symmetry of the frame and loading, to 10. The

available formulas are: Two of the type of Equation (22),

$$\theta_1 + \Delta_1 + \Delta_2 + \theta_2 = 0 \qquad (30)$$

and,

$$\theta_3 + \Delta_3 + \Delta_4 + \theta_4 = 0 \qquad (31)$$

two of the type of Equation (23),

$$\theta_1 h + \frac{2}{3} h \Delta_1 + \frac{h}{3} \Delta_2 + d_1 = 0 \qquad (32)$$

and,

$$\theta_3 s + \frac{2}{3} s \Delta_3 + \frac{s}{3} \Delta_4 + d_2 = 0 \qquad (33)$$

one of the type of Equation (24),

$$\theta_3 = - \theta_2 \qquad (34)$$

one of the type of Equation (25),

$$\Delta_3 = C_3 \Delta_2 \qquad (35)$$

one of the type of Equation (26),

$$\theta_1 = 0 \quad \text{(36)}$$

one of the type of Equation (28),

$$\theta_4 = 0 \quad \text{(37)}$$

and, one of the type of Equation (29),

$$d_2 = K_2\, d_1 \quad \text{(38)}$$

in which, $C_3 = \frac{I_1\, s}{h I_2}$ and $K_2 = -\frac{1}{\sin \alpha}$.

One more equation should be added to Equations (30) to (38) and this results from the condition of equilibrium of the joint, B, as follows:

Since $\Sigma\, X = 0$:

$$-\,T_2 \cos \alpha + V''_1 + V'_2 \sin \alpha = 0 \quad \text{(39)}$$

and $\Sigma\, Y = 0$:

$$T_2 \sin \alpha + V'_2 \cos \alpha - \frac{P}{2} = 0 \quad \text{(40)}$$

In Equations (39) and (40) T_2 is the normal stress in Member 2; V' is the shear at the left support, and V'' is the shear at the right support, with the subscript corresponding to the number of the member. After T_2 has been eliminated the tenth equation is obtained:

$$V''_1 \sin \alpha + V'_2 - \frac{P}{2} \cos \alpha = 0 \quad \text{(41)}$$

In order to be able to use Equation (41), the shears, V, should be expressed in terms of Δ:

$$V''_1 = \frac{M'_1 + M''_1}{h} = \frac{2\, E\, I_1}{h^2} (\Delta_1 - \Delta_2) \quad \text{(42)}$$

and,

$$V'_2 = -\,\frac{M'_2 + M''_2}{s} = -\,\frac{2\, E\, I_2}{s^2} (\Delta_3 - \Delta_4) \quad \text{(43)}$$

Reaction shears and reaction moments are used, with a clockwise action as positive. After substituting the expressions for V the last of the necessary equations is obtained, as follows:

$$\frac{2\, E\, I_1}{h^2} (\Delta_1 - \Delta_2) - \frac{2\, E\, I_2}{s^2} (\Delta_3 - \Delta_4) - \frac{P}{2} \cos \alpha = 0 \quad \text{(44)}$$

Solving the remaining five equations (Equations (30) to (33)) and Equation (44), the following expression is obtained for d_1:

$$d_1 = \frac{\dfrac{P}{6\,E}\cos\alpha\,(1 + C_3)\,hs^2}{-\dfrac{I_1\,s}{h}\left[\dfrac{3}{\sin\alpha} + \dfrac{s}{h}(4 + C_3)\right]\sin\alpha - \dfrac{I_2\,h}{s}\left[3\,C_3\dfrac{s}{h} + \dfrac{1 + C_3}{\sin\alpha}\right]} \quad \ldots (45)$$

Furthermore:

$$\theta_2 = d_1\left(-\frac{1}{\sin\alpha} + s\,C_3\frac{1}{h}\right)\frac{1}{\frac{2}{3}s\,(1 + C_3)} \quad \ldots\ldots\ldots\ldots (46)$$

$$\Delta_4 = \theta_2\,(1 + 2\,C_3) - 3\,C_3\frac{d_1}{h} \quad \ldots\ldots\ldots\ldots (47)$$

$$\Delta_2 = 3\,\frac{d_1}{h} - 2\,\theta_2 \quad \ldots\ldots\ldots\ldots (48)$$

and,

$$\Delta_1 = -\,\Delta_2 - \theta_2 \quad \ldots\ldots\ldots\ldots (49)$$

Substituting numerical values in Equations (45) to (49): $d_1 = -\frac{1}{E}\,954.199$; $d_3 = \frac{1}{E}\,2132.289$; $\theta_2 = \frac{1}{E}\,57.252$; $\theta_3 = -\frac{1}{E}\,57.252$; $\Delta_1 = \frac{1}{E}\,248.092$; $\Delta_2 = -\frac{1}{E}\,305.343$; $\Delta_3 = -\frac{1}{E}\,458.015$; and, $\Delta_4 = \frac{1}{E}\,515.267$.

The corresponding reaction moments will be:

$$M'_1 = \frac{2\,E\,I_1\,\Delta_1}{h} = \frac{2\,E\,3 \times 1}{E}\,248.092 = 1\,488 \text{ ft-lb} = M_a$$

$$M''_1 = -\,\frac{2\,E\,I_1\,\Delta_2}{h} = -\,\frac{2\,E\,3 \times 1}{E}\,(-\,305.343) = 1\,832 \text{ ft-lb} = M_b$$

$$M'_2 = \frac{2\,E\,I_2\,\Delta_3}{s} = \frac{2\,E\,2 \times 1}{E}\,(-\,458.015) = -\,1\,832 \text{ ft-lb} = M_b$$

and,

$$M''_2 = -\,\frac{2\,E\,I_2\,\Delta_4}{s} = -\,\frac{2\,E\,2 \times 1}{E}\,515.267 = -\,2\,061 \text{ ft-lb} = M_c$$

The foregoing example demonstrates that Mr. Stewart's method has unquestionable advantages when the supports are prevented from being displaced laterally or when these displacements are symmetrical. On the other hand, when these conditions are not fulfilled, the method becomes as complicated as the slope-deflection method, if not more so.

The writer also wishes to note the importance of revealing physical manifestation of any evolved theory, in order to simplify its understanding. The author did this in a clear and concise manner in another paper[20] when he demonstrated the similarity between the elastic line and a railway transition spiral; and also when he mentioned that the concept of the method is the product of a slope and a distance, rather than the moment of a quantity times its lever arm. These explanations appeared to the writer as being very helpful in his attempt to grasp the method.

FANG-YIN TSAI,[21] ASSOC. M. AM. SOC. C. E. (by letter).—The idea behind this method is certainly novel and ingenious. However, the writer does not consider that it furnishes "a quick and easy solution" for continuous structures, as claimed by the author.

In illustrating the application of the method, Mr. Stewart has intentionally selected several unusually simple cases most of which are rarely, if ever, met in actual practice. Undoubtedly, this was done merely to demonstrate the simplicity of the procedure, but it creates the erroneous impression that the same simple procedure can be applied also to any continuous structure in general. For instance, the simple solution of the two-legged bent in Fig. 3 does not apply when the beam and columns do not have the same length, or when the loading is not symmetrical. It may be also noted that the solution for the two-legged bent in Fig. 4 is somewhat lengthy, and does not seem as simple and direct as that by the slope-deflection method. Even for the extremely simple case of the continuous beam (see Fig. 6), the author's claim that the solution for all moments is quick and easy, does not seem to be justified. For a simple case, such as this one, the solution by the graphical method of fixed points, or conjugate points, will be found to be the quickest and easiest of all.

The method illustrated in Fig. 5 evidently applies only for the particular case of yielding supports and its application to continuous structures will be found very difficult if not impossible. Although Mr. Stewart states that "settlement of supports * * * can be incorporated in the geometry of a traverse", he has not explained how this can be done. This problem could be solved readily by Equation (3) and Fig. 2, from which it is seen that the traverse must also pass through the supports after they have settled. For illustration, the writer has solved the problem in Fig. 7, assuming that Supports B and C have settled by an amount of $d_1 = 0.2$ in. and $d_2 = 0.1$ in., respectively, relative to the elevation of Supports A and D. An 18-in 47-lb steel I-beam is assumed, with a moment of inertia, $I = 768.6$ in.^{4}, and a modulus of elasticity, $E = 30\,000\,000$ lb per sq in. The traverse is shown in Fig. 10 (c) for which the equation is,

$$\theta_1 - A_1 + \Delta_1 + \Delta_2 - A_2 + \Delta_3 + \Delta_4 - A_3 + \theta_4 = 0 \ldots\ldots (50)$$

(d) REFERRING TO EQUATION (56)

FIG. 10.

From the geometry of the moment diagram and the traverse, the following relations can be found:

$$\Delta_2 = \frac{l_2}{l_1}\,\Delta_1 \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (51)$$

$$\Delta_3 = \frac{l_2}{l_3}\,\Delta_4 \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (52)$$

$$\theta_1 = \frac{A_1}{2} - \frac{\Delta_1}{3} + \frac{d_1}{l_1} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (53)$$

and,

$$\theta_4 = \frac{A_3}{2} - \frac{\Delta_4}{3} + \frac{d_2}{l_3} \text{ ....(54)}$$

Substituting Equations (51) to (54) and the various numerical values (noting that areas of the $\frac{M}{EI}$ - diagrams due to loading are: $A_1 = 0.005$, $A_2 = 0.015$, and $A_3 = 0.00608$) in Equation (50),

$$-\ 0.1889 + 2.381\ \Delta_1 + 2\ \Delta_4 = 0 \text{ ....(55)}$$

Another equation may be obtained from the geometry of the traverse in the center span (Fig. 10 (*d*)) as follows:

$$\frac{2}{3}\ \Delta_3\, l_2 + \theta_3\, l_2 + d_2 + \frac{1}{3}\ \Delta_2\, l_2 - d_1 - \frac{1}{2}\ A_2\, l_2 = 0 \text{ ....(56)}$$

Noting that $\theta_3 = -\ \frac{A_3}{2} + \frac{2\ \Delta_4}{3} + \frac{d_2}{l_3}$, the following equation is obtained after proper substitution:

$$-\ 0.1043 + 0.571\ \Delta_1 + 1.556\ \Delta_4 = 0 \text{ ....(57)}$$

Solving Equations (55) and (57) simultaneously, $\Delta_1 = 0.00331$; $M_B = -\ 76\,000$ ft-lb; $\Delta_4 = 0.00551$; and $M_C = -\ 98\,000$ ft-lb.

The writer has also solved the same problem by the equation of three moments and the slope-deflection method, both of which are found much more simple than the method proposed in this paper. This seems quite natural since, in applying the method, the equations must be formed from the geometry of the traverse instead of by writing the slope-deflection or three-moment equations directly, to which the author objects. The writer would appreciate a suggestion for simplifying the solution of the foregoing problem.

In the "Conclusions" of the paper, Mr. Stewart states that the key constants of the analysis are simple $\frac{M}{EI}$ - diagrams and cantilever $\frac{M}{EI}$ - diagrams. It is evident that he has neglected entirely the centers of gravity of the diagrams, which are absolutely necessary, as emphasized by the author himself (see Principle (2)). This oversight is natural since the loading in all his illustrations is symmetrical for every span and, consequently, all the centers of gravity of the simple moment diagrams are known to be at the center of every span.

In discussing the application of the method to the case of variable moment of inertia, Mr. Stewart mentions the tables presented by Walter Ruppel,[8] Assoc. M. Am. Soc. C. E., and states that lists of $\frac{M}{EI}$ - areas for simple moments are unknown to him. The simple moment areas for various loading, as well as their centers of gravity, are given in Mr. Ruppel's tables. Elsewhere,[23] the writer has derived the relations between the various $\frac{M}{E\,I}$ - diagrams and the coefficients in Ruppel's tables, as follows (see Fig. 11):

$$A_L = \frac{p\,l}{I'} \tag{58}$$

$$A_R = \frac{q\,l}{I'} \tag{59}$$

$$A_o = \frac{W\,l^2}{I'}(sp + tq) \tag{60}$$

$$u = u \tag{61}$$

$$v = v \tag{62}$$

and,

$$g = \frac{tq}{sp + tq} \tag{63}$$

in which, A_L = area of $\frac{M}{I}$ - diagram due to a moment of unity applied at the left end of a simple beam; A_R = area of $\frac{M}{I}$ - diagram due to a moment of unity applied at the right end of a simple beam; A_o = area of $\frac{M}{I}$ - diagram due to loading on a simple beam; ul = abscissa of the center of gravity of A_L from the left support, L, of a simple beam; vl = abscissa of the center of gravity of A_R from the right support, R, of a simple beam; gl = abscissa of the center of gravity of A_o from the left support, L, of a simple beam; I' = minimum moment of inertia of beam; W = total load on span; l = span length; p, q, u, and v = beam coefficients in Ruppel's tables, which depend on the shape of the beam only; and s and t = load coefficients in Ruppel's tables, which depend on both the shape of the beam and the type of loading.

In Equations (58) to (63), the modulus of elasticity, E, has been omitted since it is always assumed to be constant for the entire structure. It may be noted that, for a beam with a moment of inertia varying in any manner, the following relations are always valid:

$$pu = qv \tag{64}$$

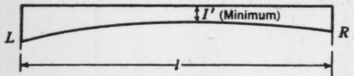
and,

$$A_L u = A_R v \tag{65}$$

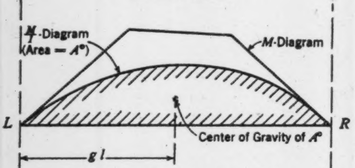
---

[23] "Theorem of Three Moments in General Form," The Science Repts, National Tsing Hua Univ., Peiping, China, Series A, Vol. II, pp. 19–36, April, 1933.

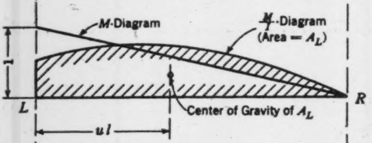
which follow directly from Maxwell's theorem of reciprocal deflections (angular). Therefore, to analyze, by any method, a continuous structure with a moment of inertia varying in any manner, five independent constants or coefficients must be known (three beam coefficients and two load coefficients) for every span of the structure considered as a simply supported beam; and these five coefficients may be expressed in various ways to suit any particular method of analysis. With the aid of Equations (58) to (63), Ruppel's tables can be utilized in applying the method to the case of variable moment of inertia.



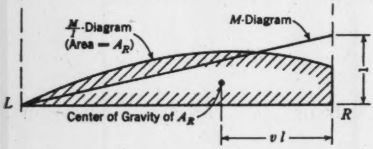
(a) Beam with Variable Moment of Inertia



(b) Moment Diagram Due to Loading



(c) Moment Diagram Due to End Moment of Unity at L



(d) Moment Diagram Due to End Moment of Unity at R

FIG. 11.

Mr. Stewart also states that,

> "From Maxwell's theorem, the final distortion of the beam from the combined action of the external forces may be treated as the sum of the distortions, due to each force acting separately."

As far as the writer knows, the statement is just one aspect of the general principle of superposition, which has not yet been attributed to Maxwell. The writer has also searched in the two volumes of "Maxwell's Scientific Papers"[23] and has failed to find anything like the theorem explicitly stated therein.

RALPH W. STEWART,[24] M. AM. SOC. C. E. (by letter).—The discussion has brought up criticisms and questions relating to specific items not satisfactorily covered in the paper. It has also raised the broader question as to whether the traverse method is a special method of limited scope, or whether it is a general method which may be used for the analysis of structures for which slope deflection and end-moment distribution are not suitable. To answer the latter query it will be necessary first to show its application to some cases of single-span beams.

Figs. 12(*a*), 12(*b*), and 12(*c*) show the simple moment areas and the positions of their centers of gravity for all conditions of normal loading; Figs. 12(*d*), 12(*e*), 12(*f*), 12(*g*), and 12(*h*) show traverse diagrams for beams of constant cross-section having various conditions of end restraint. The double hatching indicates a fixed end; the single hatching a restrained (but not fixed) end; and, absence of hatching, a hinged end. In the following equations, A is the area of the simple $\frac{M}{EI}$-diagram and Δ, the area of a triangular $\frac{M}{EI}$-diagram (not shown), with a base extending the full length of the beam and an altitude which is the end moment due to restraint, divided by E and I. If the beam has a constant cross-section and is of the same material throughout, and movements of supports are not involved, both E and I may be omitted, and the moment areas used instead of the $\frac{M}{EI}$-areas.

FIG. 12.

For these beams of constant section all Δ-angles in the traverse are at the one-third length points and $\Delta = \frac{M l}{2}$, in which M is the appurtenant end moment.

For cases in which a traverse forms a single triangle, it is often more convenient to use the angle relationships of the triangle for obtaining values of the unknowns than to write a traverse equation. In Fig. 12(d), the isosceles triangle formed by the traverse gives $\Delta = \frac{1}{2} A$, and from this, $\frac{M l}{2} = \frac{w l^3}{24}$ for uniform loading, or M (the end moment) $= \frac{1}{12} w l^2$. In Fig. 12(e), $\Delta_1 \left(\frac{l}{3}\right) = A \left(g\, l - \frac{l}{3}\right)$; and $\Delta_1 = \frac{M_1 l}{2}$. Therefore, $M_1 = \frac{2A}{l}(3g - 1)$. In Fig. 12($f$), $\Delta \left(\frac{2}{3} l\right) = A\, g\, l$; and, $\Delta = \frac{M_1 l}{2}$. Therefore, $M_1 = \frac{3Ag}{l}$. If the load is as in Fig. 12(b), then $g = \frac{1}{2}$ and $A = \frac{P l^2}{8}$, giving $M_1 = \frac{3}{16} P l$. In Fig. 12(g) (assuming counterclockwise rotations to be negative, as in slope deflection), for symmetrical loading from left to right:

$$\theta_A + \tfrac{2}{3}\,\Delta_1 - \tfrac{1}{2}\,A + \tfrac{1}{3}\,\Delta_2 = 0 \ldots\ldots\ldots\ldots\ldots\ldots(66)$$

and right to left,

$$-\,\theta_B - \tfrac{2}{3}\,\Delta_2 + \tfrac{1}{2}\,A - \tfrac{1}{3}\,\Delta_1 = 0 \ldots\ldots\ldots\ldots\ldots\ldots(67)$$

If the loading is unsymmetrical, use $A\,g$ instead of $\frac{1}{2}\,A$ in Equation (66) and $A(1 - g)$ in Equation (67). Solving these equations for Δ_1 and Δ_2, and substituting the M-values of the Δ-angles, standard slope deflection equations are obtained. When the beam and loading are symmetrical, $\phi = \dfrac{A}{2}$ and may often be used to advantage in solutions. In formulas such as Equations (66) and (67) only the coefficients of l are used as l, if written in each term, will be eliminated.

In Fig. 12(h) a dominating moment in an adjoining span has reversed the direction of the end slope, θ_B. This will be discussed subsequently.

Fig. 13 illustrates the traverse of a beam of variable section and complete dissymmetry having fixed ends. All dimensions and properties of this beam have been presented[25] by George E. Large, Assoc. M. Am. Soc. C. E., including the computations for the A and Δ locations and magnitudes.

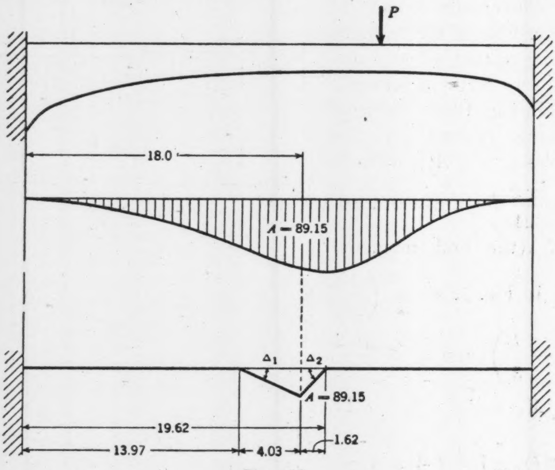

FIG. 13.

From the triangle in the traverse: $\Delta_1 = \dfrac{1.62}{5.65} \times 89.15 = 25.56$; $M_1 = \dfrac{25.56}{9.12} \times 10 = 28.00$; $\Delta_2 = \dfrac{4.03}{5.65} \times 89.15 = 63.59$; and $M_2 = \dfrac{63.59}{12.27} \times 10$

---

[25] "The Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 102; also, *Bulletin No. 66*, Ohio State Univ.

= 51.83. This solution gives the fixed-end moments by a simpler procedure, involving less computation, than the previously published solution.[36] Problems of the fixed-end moments in restrained beams cannot be solved by slope deflection or by end moment distribution. Their solution as herein demonstrated shows that the traverse method is applicable to fundamentals.

Frequently, in a continuous beam, the direction of rotation at a support cannot be forecast by inspection, and the question arises as to how to apply the traverse. This condition is illustrated by Fig. 14, in which the slopes over the intermediate supports are purposely drawn in the wrong direction. The procedure for drawing the traverse lines is described in connection with Fig. 7. Before the sketch is completed, it announces the error in assumption by the disproportionate sizes of the *A*-angles. Disregarding this, now obvious, error in the diagram, write the traverse equation from left to right and from right to left for the full length of the beam; combine the numerical terms and the coefficients of the respective Δ-angles; and obtain: $28\,\Delta_1 + 30\,\Delta_2 = 2\,160$; and, $-12\Delta_1 - 26\,\Delta_2 = -1\,620$. (The signs in these equations follow the rules for slope deflection.) Solving, $M_B = 6.85$ and $M_C = 17.61$. Continuing the solution it is found that $\theta_B = -\dfrac{8.80}{EI}$ and

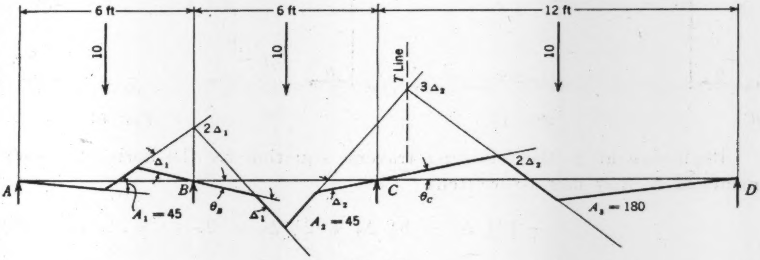

FIG. 14.

$\theta_C = +\dfrac{19.57}{EI}$. The solution was not affected by the error in the diagram. Attention is invited to the fact that a mechanical solution of this problem could be obtained by drawing the *A*-angles to a suitable scale on separate slips of tracing paper and manipulating them with their legs intersecting on the *T*-lines until proper closure is obtained. The result would be rather rough, but probably more accurate than that obtained by using the arbitrary coefficients of various building ordinances.

The fact that a computed traverse can be checked quickly by plotting, and that errors in assumed direction of joint rotations are disclosed while the traverse is being drawn, is an advantage of no small importance, which is not available with other methods.

The discussion of Mr. Nelidov shows comprehensive understanding of the traverse method and also shows that it can be applied to frames with sloping roof members. In order to do the method justice, however, it will be necessary to show a shorter and simpler solution of the problem that he presented. Fig. 15 shows (in its deflected position) the same frame and loading as Fig. 9, the right half indicating the elastic curvature and the left half, the traverse diagram. The value of Δ_3 results from the relative stiffness factors of the column and the rafter. The value of Δ_4 is obtained by summation of angles from Δ_1 upward.

FIG. 16.

Beginning at Δ_1 the following traverse equation for the horizontal movements of Δ_4 may now be written:

$$-13\tfrac{1}{3}\,\Delta_1 + 8\tfrac{1}{3}\,\Delta_2 + 2\tfrac{1}{2}\,\Delta_3 = 0 \ldots\ldots\ldots\ldots\ldots (68)$$

For the left half of the frame two moment-shear equilibrium equations—one for the column and one for the rafter—may be written as follows:

$$M_1 + M_2 = 15\,H \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (69)$$

and,

$$M_3 + M_4 = 500 \times 10 - 5\,H \ldots\ldots\ldots\ldots\ldots\ldots (70)$$

in which H equals the horizontal thrust caused by the load. After transforming M-values to Δ-values, Equations (68), (69), and (70) are easily solved, giving $H = 220.1$, and moments which agree with those found by Mr. Nelidov. (Moment-shear equilibrium formulas of the type of Equations (69) and (70) are used in the analysis of wind stresses in buildings. The principle is that the shear in a column is equal to the sum of its top and bottom moments divided by its height.)

No trigonometric functions are necessary in this solution, the number and size of equations are less impressive, and the labor is reduced.

Several discussers thought that the original paper was confined too much to symmetrical structures and loading. The following illustrations will show that the traverse method readily solves unsymmetrical cases. Fig. 16 is introduced because its solution may be checked conveniently by other methods or by handbooks. It will serve to illustrate the method of approach to the general case which succeeds it.

If the columns in Fig. 16(*a*) were on rollers the beam would deflect as if it were simply supported. The joint rotations would be equal to the end slopes of the simple beam, and the spread, $d_0 = d_1 + d_2$, at the bottoms of the columns would be equal to the sum of the end slopes times the height of the frame, which is equal to the area of the $\frac{M}{EI}$ - diagram for the beam (considered as simply supported) times the height of the frame. For equilibrium, since the column bases do not spread, a force, H, must be exerted with a magnitude sufficient to produce inward deflections of the columns equal to the spread, d_0, as indicated in Fig. 16(*b*). Thus, in Fig. 16(*a*),

$$d_1 + d_2 = d_0 = Ah = \frac{P\,a\,b\,h}{2\,I_2}$$

and, in Fig. 16(*b*),

$$d_3 = 2\,(\Delta_1 \times \tfrac{2}{3}\,h) + 2\,\Delta_2\,h = \frac{2\,H\,h^3}{3\,I_1} + \frac{H\,h^2\,l}{I_2}$$

Equating d_0 to d_3; letting k = the ratio of the stiffness of the beam to the stiffness of the column $= \frac{I_2\,h}{I_1\,l}$; and solving for H,

$$H = \frac{3\,P\,a\,b}{2\,h\,l\,(2\,k + 3)} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(71)$$

which is a handbook formula.[27] With H known, the moments are statically determinate. This solution takes into account the effect of side-sway.

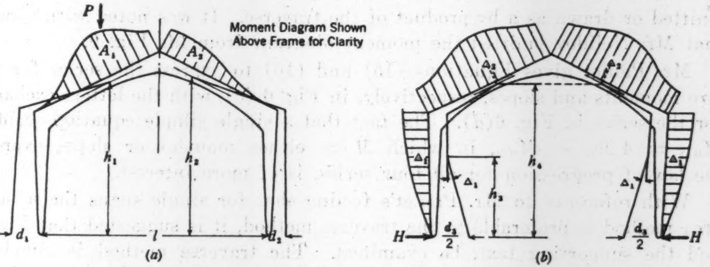

FIG. 17.

Fig. 17 shows unsymmetrical loading for a hinged-base, gable roof frame of variable moment of inertia. Following the method of approach indicated for Fig. 16, the equations by which this frame may be solved are, as follows:

---

[27] "Rahmenformeln," von A. Kleinlogel, Wilhelm Ernst & Son, Berlin.

In Fig. 17(*a*),

$$d_1 + d_2 = d_0 = A_1 h_1 + A_2 h_2 \qquad (72)$$

For a trial H in Fig. 17(*b*), compute,

$$d_3 = 2\,(\Delta_1 h_3 + \Delta_2 h_4) \qquad (73)$$

and,

$$\text{True } H = \frac{d_0}{d_3} \times \text{trial } H \qquad (74)$$

With H computed, the problem becomes statically determinate. This solution also includes the effect of side-sway.

These applications of the traverse method show that it is not restricted in its scope as are slope deflection and end-moment distribution. The latter methods require the assistance of some other type of analysis to obtain the fixed-end moments needed. They are also unsuitable for frames with sloping roof members. The traverse method is applicable to the entire field of flexure, in which moments only and straight members only are involved. Even where axial shortening of members is involved the traverse can be passed through the altered positions of the joints as shown by Fig. 10, and solved. The method, therefore, appears to be entitled to the adjective, "general," rather than "special."

Mr. Paulet feels that the bending-moment diagram should be available as a guide, so that the traverse can be sketched. Proper observance of laws governing the angles will make it as easy or easier, to draw the traverse independently.

Note that in all diagrams each obtuse angle which is the supplement of each A-angle presents its opening toward the load, and if there is restraint to resist free rotation of an adjoining joint, there will be a Δ-angle of opposite direction between the A-angle and the joint. Using this rule the writer finds it easier to draw the traverse first, the moment diagram being either omitted or drawn as a by-product of the traverse. It was noted with pleasure that Mr. Nelidov omitted the moment diagram from his Fig. 9.

Mr. Paulet gives Equations (15) and (16) to express the series for relative moments and slopes, respectively, in Fig. 6 (*c*), with the letters exchanged for the series in Fig. 6(*d*). The fact that a single simple equation—namely, $M_{n+1} = 4\,M_n - M_{n-1}$, in which M = either moment or slope—expresses the law of progression for all four series, is of more interest.

With reference to Mr. Paulet's feeling that for single spans the moment-area method is preferable to the traverse method, it is suggested that Fig. 13, and the supporting text, be examined. The traverse method is simply an amplification of the moment-area method by expressing moment-area relationships as a geometrical traverse, which clarifies the computations, discloses "short cuts" which would not be evident except for the traverse diagram, provides a graphical check, and also an easily understood method of treating settled supports.

The statement by several discussers that the traverse method compares unfavorably in speed with other methods merits a brief investigation. The solution for Fig. 3 was presented in complete detail to illustrate the principle of the traverse. A computer familiar with the method would not write Equation (6), but would analyze the traverse as follows: In Fig 3 where two lines intersects to form a Δ or A-angle, note that the intersection displays both an acute angle (the Δ-angle or the A-angle) and an obtuse angle which is the supplement of the Δ-angle or the A-angle. Designate angles with obtuse openings that face the interior of the frame as negative and the angles with obtuse openings that face outward, as positive. The sum of the negative angles must equal the sum of the positive angles. Noting that each column traverse forms an isosceles triangle, the computer can add the angles mentally and write, $3\,\Delta_2 = \dfrac{P\,l^2}{8\,E\,I}$. The subsequent steps can also be performed by mental arithmetic.

FIG. 19.

A good illustration of the speed of the traverse method is given by Fig. 18 which is the demonstration problem used by T. Y. Lin, Jun. Am. Soc. C. E., in his paper "A Direct Method of Moment Distribution."[28] Let Δ equal the curvature in the bottom member due to one of its end moments. Then Δ will also equal the rotation at each bottom corner. From the stiffness ratios the curvature due to the moment in the bottom of the column will be $2\,\Delta$, as shown. The fixed-end moment of 1 000 at the end of the top member gives a ϕ-angle of 167, as shown. The solution is now given by the following equations: Traversing from the bottom to the top of the column, $-3\,\Delta - 4\,\Delta + \Delta_4 = 0$; and, therefore, $\Delta_4 = 7\,\Delta$. The upper joint rotation, by adding angles from the bottom to the top of the column, is equal to $4\,\Delta$; the curvature due to the end moment in the beam, by stiffness ratios, will be $\frac{7}{3}\Delta$; and the closure of the triangle under the end of the upper beam gives, $\frac{19}{3}\Delta = 167$, from which $\Delta = 26.32$, and the bottom and top moments in the column are, respectively, 105.2 and 368.2. This is a direct solution which appears to the writer to be more expeditious than the previous solution cited and will compare well with solutions by slope deflection or by progressive end-moment distribution.

---

[28] *Proceedings*, Am. Soc. C. E., December, 1934, p. 1460.

Fig. 19 illustrates a two-story frame with members all of which have equal stiffness factors and joint rotations with unknown directions. Assume the direction of joint rotations as shown, and write, by inspection, all the angle values shown on the diagram, the Δ-value at the lower third point of the upper column being obtained by balancing moments about the adjoining joint.

Upward and downward traverses of the upper column now give:

$$\left(\frac{Q\,l^2}{16} - \Delta_2\right) - \frac{2}{3}\left(3\,\Delta_2 - \frac{Q\,l^2}{8}\right) + \frac{1}{3}\,\Delta_3 = 0$$

and,

$$\left(\frac{P\,l^2}{16} - \Delta_3\right) - \frac{2}{3}\,\Delta_3 + \frac{1}{3}\left(3\,\Delta_2 - \frac{Q\,l^2}{8}\right) = 0$$

Solving,

$$\Delta_2 = \frac{P\,l^2}{224} + \frac{11\,Q\,l^2}{224}$$

The rotation at the left end of the lower beam is $-\frac{P\,l^2}{224\,E\,I} + \frac{3\,Q\,l^2}{224\,E\,I}$. Therefore, if $P < 3Q$, the rotation is positive, as shown, and if $P > 3Q$, the rotation is counter-clockwise.

Continuing the solution it is found that if $Q > 5P$, the left top corner of the frame will rotate contra-clockwise. It is observed that slope-deflection sign rules may be applied to the traverse method of solving problems involving unknown directions of joint rotations.

Mr. Mitchell showed an application of the traverse method to Fig. 3, assuming that the column bases are 50% fixed. The traverse method, however, offers a shorter solution than that given by him, as follows: For the columns fully fixed at the base, $\Delta_1 = \frac{1}{2}\,\Delta_2$. For 50% fixation, Δ_1 will become equal to $\frac{1}{4}\,\Delta_2$ and a rotation will occur at the bottom of the column which will be two-thirds of the change in the value of $\Delta_1 = \frac{1}{6}\Delta_2$.[29] This angle of rotation will present its obtuse opening outward the same as Δ_1. Equating the sum of the negative angles around the frame to the sum of the positive angles, one may write at once $3\frac{1}{6}\Delta_2 = \frac{P l^2}{8}$, from which $M = \frac{3}{38} P l$, agreeing with Mr. Mitchell's result, but doing away with his Equations (17), (18), and (19), and his traverse equation.

The writer cannot agree with Mr. Mitchell that the traverse method "holds no advantage over the slope-deflection method", nor with his findings as to the number of equations required.

Professor Tsai indicated in his discussion that he had fully grasped the traverse method. His equations showing how simple moment areas and the positions of their centers of gravity may be derived from (although not "given in") the Ruppel tables[6] constitute a useful contribution to the practical application of the method. His comment that he could use the equations of three moments involving settled supports or the slope-deflection method with greater facility than the traverse method to solve Fig. 10, indicates that for this problem it is easier to apply ready made formulas than to work from basic principles, provided the formulas are memorized.

Professor Wilson has also grasped the traverse method, but leans to the end-moment distribution method as "the most workable of the special methods". In this connection it is worth noting that Hardy Cross, M. Am. Soc. C. E., has stated[30] that for single bents he preferred the column analogy method[31] to the end moment-distribution method. The traverse solutions for single-span frames, including arched frames as given herein, should certainly compete with the column analogy, especially for frames of variable moment of inertia to which the Ruppel tables are applicable.

The writer thanks Professor Drummond, Mr. Reeves, Mr. Kirkbride, Professor R. B. Ketchum, and Mr. Floris for their interest and the last three particularly for their encouraging comments. He feels that considering the versatility and general applicability of the traverse method, it should gain recognition.

It is superior to slope deflection in the following respects: (1) It provides an easy graphical verification of the computed analysis; (2) it uses basic principles rather than memorized formulas ("the anæsthetics of thought"); (3) it does not require the assistance of some other method; and (4) the entire elastic deformation of a structure may be pictured from the solution by the traverse method.

It is superior to end-moment distribution in Items (3) and (4), and also in its utility in deriving a specific formula which may be recorded for future use.

RELATION BETWEEN RAINFALL AND RUN-OFF FROM SMALL URBAN AREAS

By W. W. Horner,[1] M. Am. Soc. C. E., and
F. L. Flynt,[2] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Franklin F. Snyder, Merrill M. Bernard, LeRoy K. Sherman, and W. W. Horner and F. L. Flynt.

Synopsis

The results of research into the relation between rainfall and run-off from small urban areas in St. Louis, Mo., are here presented as specific studies of the run-off from parts of two different city blocks tributary to street inlets and from both roofs and ground surface of another entire city block. The information submitted results from measurements of rainfall and storm flow for practically all heavy rains occurring from 1914 to 1933. The ratio of run-off to rainfall, defined in several ways, is shown to vary over a wide range.

Rainfall rates at each of the locations studied are reduced and developed into frequency diagrams, and these three rainfall studies, with one other, are combined into a master frequency study for the general region. Run-off is also studied as an independent phenomenon; the run-off frequency curves are developed in a form similar to the rainfall diagrams.

The two sets of curves are considered to be comparable as representing equivalent probabilities of occurrence. Ratios are then developed between corresponding values. Within certain limits, it is suggested that these ratios may be applied to proper rainfall frequency curves for other localities and will give approximate run-off values for similar conditions of surface.

Suggestions are offered as to how the values determined for specific blocks in St. Louis might be modified further to be applicable to (*a*) different

surface slopes; (*b*) other percentages of impervious area; and (*c*) other typical soils. For Class (*c*), adaptation factors are determined by sprinkling, at definite rates, a number of segregated areas of bare soil and of turf.

INTRODUCTION

In 1908, one of the writers had developed an application of the rational method of sewer design for the City of St. Louis. The form of treatment and the mechanics of the application were considered satisfactory; but there was little information then available as to necessary ratios between rainfall and run-off under specific conditions. A proper development of the hydrology of urban drainage required the provision of dependable factors indicating the relation between rainfall and run-off for a wide range of situations.

FIG. 1.—LOCATIONS OF OBSERVATION STATIONS AND TIPPING-BUCKET RAIN GAUGES.

Funds were made available by the City of St. Louis for a research program. In 1910, three tipping-bucket rain gauges were installed in the 500-acre Clarendon drainage area (see Points 1, 2, and 3, Fig. 1), and about ten water-level gauges in its main trunk sewer. The information thus secured was analyzed in part in 1915 and, again, in 1920, but not exhaustively. Tentative values were deduced and the resulting run-off factors have been used in St. Louis, but, heretofore, no thorough study has been completed to a degree justifying publication of the results.

When the characteristics of the flow in the main trunk sewer came to be scrutinized, it was apparent that a closer view of the basic relations might be secured from an examination of the run-off phenomena from smaller areas. Therefore, a study was undertaken of two inlet areas at Belt and Ridge Avenues and at City Block No. 4841 (Stations *A* and *B*, Fig. 1), involving the run-off from entire city blocks, exclusive of that from the roofs of residential buildings. Later, a gauge was installed in a lateral sewer near Ewing and Washington Avenues (Station *C*, Fig. 1), and the entire run-off of a third block, including that from roofs, was made available for analysis. The result of observations in these three city blocks, during heavy rains, is presented herein.

In the course of this more detailed study, a better acquaintance with the effect of soil characteristics and conditions upon run-off became desirable. Impressed with the simplicity of the sprinkling tests, made by the Miami Conservancy District, a similar series of tests were conducted in St. Louis, using somewhat more elaborate and refined methods. The result of a part of this work has been published.[3] All the data are given in the unpublished Appendices filed in Engineering Societies Library, 29 West 39th Street, New York, N. Y. Included with these records is also the result of a similar series of tests, conducted under the supervision of one of the writers, in connection with the studies for storm-sewer design for Dallas, Tex.

garages, the only one of importance resulting from the erection of an apartment house at the corner of Belt and Ridge Avenues. The data for the beginning and the ending of the test period are shown in Table 1.

FIG. 5.—TYPICAL APPEARANCE OF PROPERTY INVOLVED: (a) AREA A; (b) AREA C.

Description of Instruments for Inlet Area Tests.—At each location the run-off was measured by recording the head on a 90°, V-notch weir of $\frac{3}{8}$-in. steel plate with bronze edges. At Station *A* and for Station *B*, the weir was installed in a special chamber built as an extension of the bowl of the catch-basin. At Station *C*, the weir was installed in a chamber built into the brick sewer itself. In each instance, the head on the weir was measured by a pressure bulb connected with a recording clock gauge.

In Fig. 2, 30% of the area above the inlet at the northwest corner of Belt and Minerva Avenues is assumed to be tributary to the gauge at Belt and Ridge Avenues for all rains. Referring to Fig. 3, the area marked, *D*, was judged to yield practically no run-off. The yard marked, *E* (Fig. 3), was found to have several small sumps, so that water from this yard did not reach the gauge. Consequently, it was assumed that water from all storms would probably stand.

At Station *C* (see Fig. 4), the rainfall was measured by a standard tipping-bucket gauge on a building adjacent to the upper edge of the block. At Stations *A* and *B*, home-made rain gauges were installed in such a way that the rain water falling into the gauge was measured as head on an additional pressure bulb, which actuated an extra pen installed on the clock gauge. These rain gauges were calibrated by introducing known quantities of water into the stand-pipe and noting the chart records. To supplement these gauges, three tipping-bucket rain gauges were also available at Shawmut and Ridge Avenues, at Kingshighway and Enright, and at Union and Patton Avenues, all within a mile of the two home-made gauges

PERVIOUS AREA

At Area *A,* Fig. 2, the pervious part consists of small front lawns, some good turf, and some bare soil. At Area *B,* Fig. 3, nearly all the pervious part is well turfed. At Area *C,* Fig. 4, the pervious part consists generally of some small separated plots of rather hard-packed soil.

Reduction of Records.—An examination of a typical chart for Belt and Ridge Avenues (Fig. 6) shows the rain pen moving from the outer circle toward the center, and the weir pen moving outward from the center. Celluloid verniers, indicated by the shaded rectangular areas, make it possible to read the time scales to the nearest minute. Since the rain pen is a home-made addition to the gauge, it does not follow the printed time lines, and the apparent time of the rain record must be corrected to clock time. Fig. 7 shows the curves obtained by plotting the information obtained from charts, such as Fig. 6. The records for City Block No. 4841 were similarly reduced and plotted; the tipping-bucket rain gauge at Station *C* necessitated some differences in the detail of handling its records.

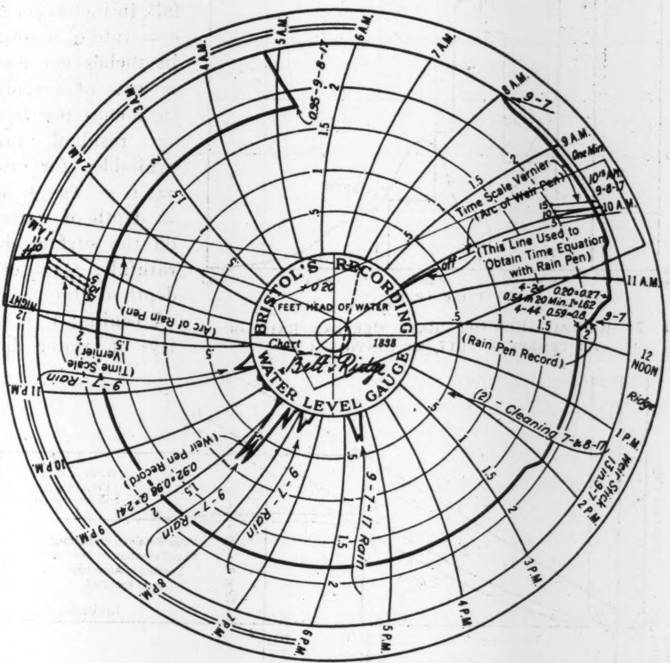

FIG. 6.—RAINFALL AND RUN-OFF RECORD, STATION *A*;
RAIN OF SEPTEMBER 7, 1917.

Run-Off Characteristics.—To introduce the factors that enter into the rainfall-run-off problem, the following discussion of a hypothetical case is offered.

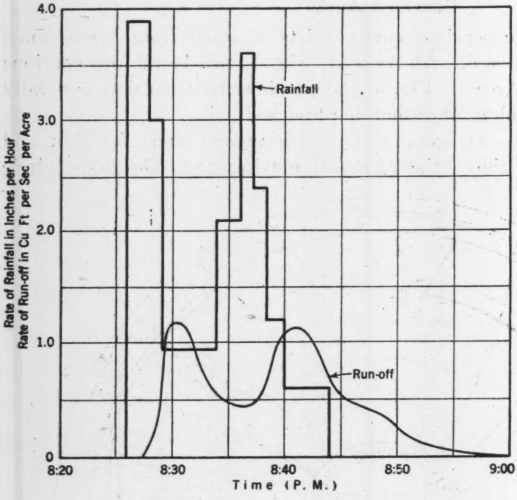

FIG. 7.—RAINFALL-RUN-OFF RATE CURVES; RAIN OF SEPTEMBER 7, 1917, AT STATION *A*.

Fig. 8 represents the case of an inclined plane with a pervious surface, exposed to a rainfall of uniform rate. Let i = intensity, or rate of rainfall, in inches per hour; a = rate of absorption, in inches per hour; e = rate of evaporation in inches per hour; I = residual rainfall available for run-off $= i - (a + e)$; f = depth of water film on the surface due to rainfall; f_c = critical depth of film when run-off begins; V = velocity of water in the

FIG. 8.—RELATION BETWEEN RAINFALL AND RUN-OFF.

moving film; Q = rate of run-off; and t = duration of a rain. Point A represents the beginning of the rainfall. For a time, the rate, $(a + e)$, is greater than i and no water can accumulate on the surface; but since i is constant and $(a + e)$ is decreasing, eventually $(a + e) = i$, as at Point C, Fig. 8, when the surface film begins to form and I begins to have a positive value. The water in this film is subject to two opposing forces: (1) A component of the force of gravity which tends to cause motion on the plane; and (2) surface tension which tends to oppose this motion. As the rate, $(a + e)$, decreases, the depth of film, f, increases until the critical depth, f_c, is attained, as at Point E, Fig. 8, when run-off begins. Under the assumed conditions, run-off would begin simultaneously over the entire area.

Frictional resistance, which tends to reduce acceleration, increases with the velocity and decreases with the depth. Therefore, the values of f and V at any given point on the plane depend on a balance between these opposite effects combined with the effects of absorption and evaporation.

If the assumed conditions continued for an indefinite time, the value of $(a + e)$ would approach zero as a limit, and the values of I and Q would approach i as a limit, as indicated in the diagrams by Points B', D', and F', Fig. 8. From this time on, the product, $f \times V$, at all points on the plane would be constant, as would the total volume of water in transit, represented by the intercept on the ordinates between the lines, CD and EF, on Fig. 8(a).

If, however, rainfall should cease after a time, t, the value of i would drop immediately to zero as indicated by the line, BH, in Fig. 8(b). The water in transit, represented by the line, DF, in Fig. 8(a), would still be available for run-off which would continue at a decreasing rate until the moving film was reduced to the critical depth, f_c, as at Point G, when run-off would cease; the water retained would eventually be absorbed or evaporated.

Actual Areas.—Many factors not considered in the hypothetical case are involved in an actual inlet area. It is not a plane surface, but a collection of small contiguous planes; the slopes may range from horizontal for tennis courts, to vertical for building walls; the permeability of the component surfaces may likewise vary over a wide range, from asphalt street paving to grass plots and cultivated ground. The actual area may contain well-defined watercourses, such as gutters and rivulets.

Depressed areas may be present into which water drains and thus becomes trapped; this drainage never reaches the inlet, but eventually is absorbed or evaporated. Such a condition may be designated as retention by pondage. If the depression is shallow, it may soon be filled and then contribute its overflow to the run-off; or, the depression may have an outlet that is too small to drain the water as fast as it falls. This water will appear in the total run-off, but its detention will have an effect upon the rate of run-off.

Although an actual inlet area may be composed of elemental plane surfaces, it is impracticable to analyze run-off from each small area separately. The entire inlet area is here taken as a unit, and the run-off from it is studied as a whole.

Unit Graph.—Fig. 9 is a typical example of a rainfall-run-off graph as derived from the local records. A study of these graphs shows that the reduction in height of the run-off peaks, as compared with the rainfall peaks, is not entirely due to the loss of water by absorption and evaporation. It is due partly to the fact that run-off is spread over a greater time interval than rainfall. If some method could be found to separate these two rate-reducing effects of loss by absorption and of distribution of the run-off in time, it would be possible to measure the absorption and evaporation characteristics of the areas under investigation.

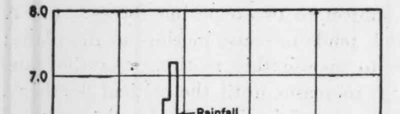

FIG. 9.—RATE CURVES FOR RAINFALL AND RUN-OFF, STATION *C*; RAIN OF SEPTEMBER 7, 1920.

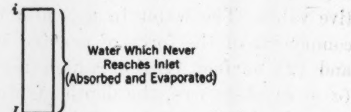

FIG. 10.—UNIT GRAPH REPRESENTING THEORETICAL RUN-OFF RESULTING FROM RAINFALL ON UNIT AREA FOR UNIT TIME.

Following is an outline of a method of analysis based upon a theoretical unit graph showing the probable distribution in time of the run-off resulting from 1 min of uniform rainfall.

In Fig. 10, the rectangle, *Oi,* represents the volume of 1 min of uniform rainfall. The rectangle, *OI,* represents the volume of this rainfall which will ultimately reach the sewer.

The shape of the run-off unit graph was derived from a study of the records of a few short rains of fairly uniform intensities, the equations for the two branches being entirely empirical. The quantities, Q_a and Q_d, respectively, are the ascending and descending instantaneous values of Q resulting from a rainfall of unit duration on a unit area; Q_m is the maximum value of

Q_a and Q_d; t is the time measured from the beginning of the rainfall; t_l is the lag, or the value of t at Q_m; and j and k are arbitrary constants. For the increasing values of Q, the equation of the line, OA, is:

$$Q_a = Q_m \left(\frac{t}{t_l}\right)^j \qquad \text{(1)}$$

For decreasing values, the equation of the line, AB, is:

$$Q_d = \frac{Q_m}{k^{t-t_l}} \qquad \text{(2)}$$

From Equations (1) and (2) it is seen that when $t = t_l$, $Q_a = Q_d = Q_m$.

Integrating and adding Equations (1) and (2), the area under the unit run-off curve is found to be:

$$I = Q_m \int_0^{t_l} \left(\frac{t}{t_l}\right)^j dt + Q_m \int_{t_l}^{\infty} \frac{dt}{k^{(t-t_l)}} = Q_m \left(\frac{t_l}{j+1} + \frac{1}{\log_e k}\right) \qquad \text{(3)}$$

Since $I = Pi$, the value of Q_m is found to be:

$$Q_m = \frac{Pi}{\left(\dfrac{t_l}{j+1} + \dfrac{1}{\log_e k}\right)} \qquad \text{(4)}$$

The values, j and k, in Equations (1) to (4) can be determined only by trial. After many rains had been investigated, it was found that, for Stations A and B, values of $j = 1.0$ and $k = 1.2$ and, for Station C, values of $j = 2$ and $k = 2$ gave the best results (see Fig. 11).

TABLE 2.—COMPUTATION OF 100% RUN-OFF CURVE, OR VALUES OF Q_c (SEE FIG. 12)

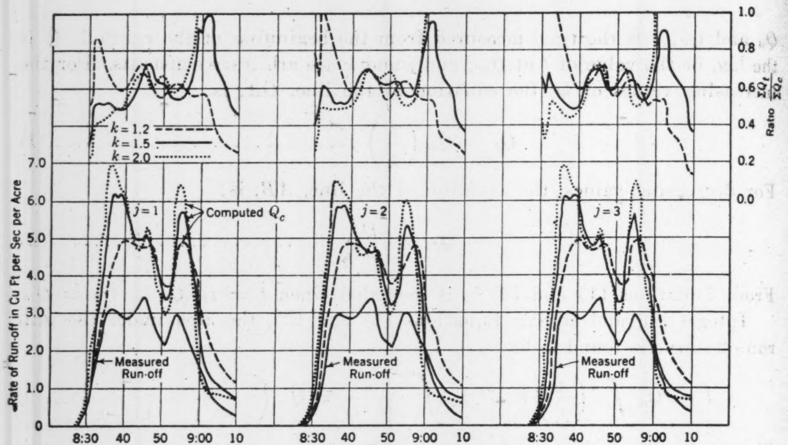
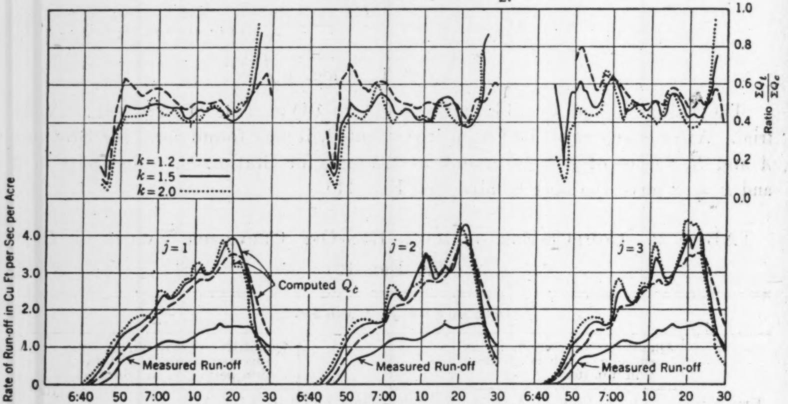
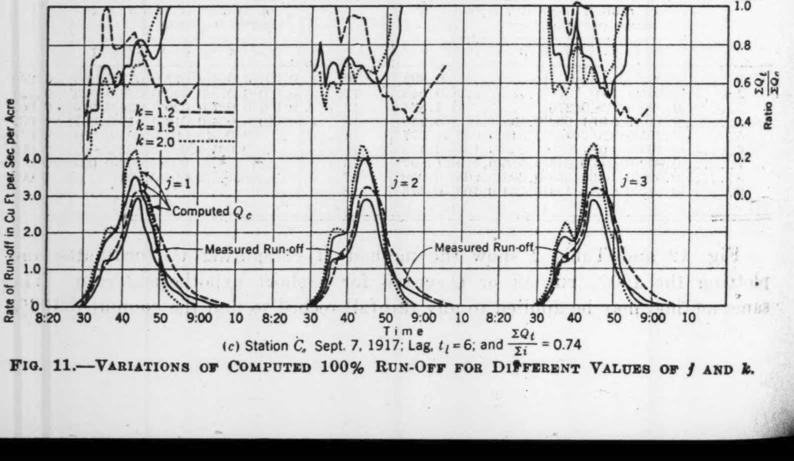
Fig. 12 and Table 2 show the method of computing the ordinates and plotting the 100% run-off or Q_c-curve for a short hypothetical rain. The same method may be applied to any rainfall record to find the computed 100%



(a) Station A, Aug. 8, 1923; Lag, $t_l = 4$; and $\frac{\Sigma Q_t}{\Sigma i} = 0.56$



(b) Station B, Aug. 27, 1921; $t_l = 8$; and $\frac{\Sigma Q_t}{\Sigma i} = 0.49$



(c) Station C, Sept. 7, 1917; Lag, $t_l = 6$; and $\frac{\Sigma Q_t}{\Sigma i} = 0.74$

FIG. 11.—VARIATIONS OF COMPUTED 100% RUN-OFF FOR DIFFERENT VALUES OF j AND k.

run-off for any area for which the lag is known. The computed Q_c-curve shows the rate-reducing effect of the distribution of run-off, in time, separated from the effect due to absorption and evaporation. A comparison of the measured run-off curve with the 100% run-off curve shows the effect of absorption and evaporation.

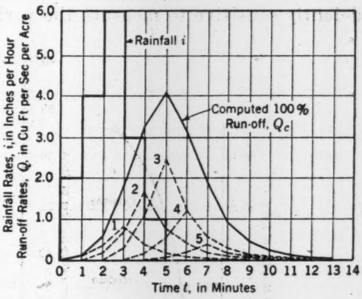


FIG. 12.—HYPOTHETICAL RAIN, SHOWING APPLICATION OF UNIT GRAPH (SEE TABLE 2).

Lag.—The term, "lag", as used herein has reference only to the difference in phase between salient features of the rainfall and run-off rate curves; its numerical values (which are generally somewhat less than the "time of concentration") are difficult to determine with the desired accuracy owing to the limitations of the recording instruments. (A full discussion of this subject is included in the record manuscript filed in Engineering Societies Library.) Observed values, subject to correction, are taken from the time difference between salient features of the rainfall and run-off rate curves; or between the centers of mass of the rainfall and run-off rate curves.

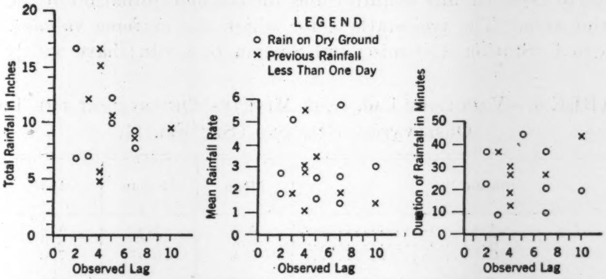

FIG. 13.—TYPICAL CORRELATION DIAGRAMS FOR LAG AT STATION *A*.

The comparatively wide range in the lag at each location led to the inference that the lag was a variable, its value being determined more by rainfall characteristics than by the characteristics of the drainage area. Diagrams were made of the relation between the lag and various rainfall characteristics (see Fig. 13), but no evidence of correlation was found. On all these diagrams, the values of the lag for each location tended to be concentrated about certain modal values. A statistical study (see Fig. 14) indicated that the mean, the median, and the modal values of the lag for each location were approximately equal, which suggested that the value was nearly constant for each station, and that the variations from the mean value were probably chance variations which were partly explained later by the discovery of small unsuspected time errors. Each of the plotted points through which the curves in Fig. 14 were drawn, represents the number of storms investigated which had the corresponding observed value of lag, or less. Values of the lag as observed at the three observation stations are given in Table 3. Under certain circumstances, the true lag may vary slightly from the adopted values in Table 3, but the recording instruments available for this work are not sufficiently sensitive to measure the variation with any assurance of accuracy.

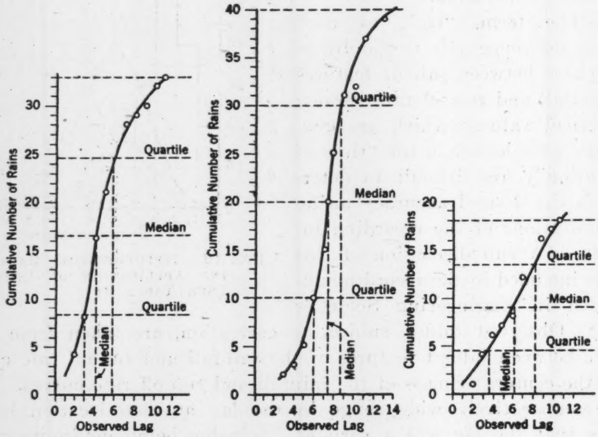

FIG. 14.—OGIVE CURVES SHOWING VARIATION IN OBSERVED VALUE OF LAG; (*a*) STATION *A*; (*b*) STATION *B*; (*c*) STATION *C*.

As only three different areas are represented in the local records, it is impossible to establish any definite rules for the determination of the lag for a given inlet area. The two stations for which the extreme values of the lag are indicated (Station *A*, 4 min; and Station *B*, 8 min) have widely different characteristics. The conditions of size and shape which tend to increase the lag are combined with conditions of slope which have the same tendency. This makes it difficult to separate their effects, but it does give an idea of the maximum range of value of the lag for similar areas.

TABLE 3.—VALUES OF LAG, t_l, IN MINUTES, OBSERVED AT THE THREE OBSERVATION STATIONS (SEE FIG. 1)

Station	Mean	Median	Mode	Adopted value
A	5.3	4.1	4.0	4
B	8.3	7.5	8.0	8
C	6.4	6.1	7.0	6

Drainage Area *C* (Fig. 4) includes several independent inlet areas and considerable roof drainage, and the storm water from all parts of the block reaches the sewer after a comparatively short run. At the other stations, the flow is entirely over the surface to the point of measurement. For this reason a direct comparison cannot be made with the other locations, but the results indicate that the lag for a completely sewered area is practically the same as that for a simple inlet area of comparable size.

The majority of inlet areas, at least in St. Louis, would have lags somewhere between 4 and 8 min. For any ordinary inlet area, a lag of 5 min could not be very far from the true value.

DETERMINATION OF THE RUN-OFF FACTOR

The 100% Run-Off Graph.—The rates of 100% run-off, computed by the same method as shown in Fig. 12 and Table 2, have been plotted as broken lines in Fig. 15 for a typical storm at each station. The lines represent the theoretical value of the run-off rate for an absolutely impervious area if there is no evaporation. Their close similarity to the measured run-off curves is obvious; the infrequent dissimilarities are due to several causes. For example, the factors, j and k, in the formulas may be slightly in error due to the difficulty of ascertaining these values. There is a possibility that the rate of rainfall for single minutes may be in error, although the average rate for several minutes may be correct. Furthermore, there may be slight time errors which would tend to shift the rainfall and run-off peaks one way or the other. All these causes would affect the shape of the Q_c or 100% run-off curve and, in some cases, their effects might be cumulative and appreciable.

Except as otherwise stated, the run-off factor, P, is defined as the ratio between ΣQ_t, the volume of water that has run off from the given area to a given time, and ΣQ_c, the volume of water that would have run off from the area during the same time had there been no evaporation or absorption. It is indicated most conveniently (see Fig. 16) by the ratio between corresponding ordinates of the mass curves of the measured run-off and the 100% run-off. (In Figs 16(a) and 16(b), the ΣQ_c-curve would eventually meet the Σi-curve if the entire record had been plotted.)

Typical Storms.—The storm of September 8, 1926, on Area A (see Fig. 15(a)) begins with a period of high intensity lasting for about 6 min; then it falls suddeuly to medium values which gradually decrease with some minor fluctuations until the end of the storm.

The ordinate to the mass curve, $\frac{\Sigma i}{60}$ (Fig. 16(a)) for any given time is proportional to the area of the rainfall-rate curve from the beginning of the rain to the given time. Similarly, the $\frac{\Sigma Q_c}{60}$ and $\frac{\Sigma Q_t}{60}$ -curves are the mass curves for the 100% run-off and the measured run-off, respectively.

The graph of the run-off factor, $P = \frac{\Sigma Q_t}{\Sigma Q_c}$, is obtained from the ratio of corresponding ordinates of the mass curves. The comparatively large difference between the maximum and final values of the run-off factor in this case is rather unusual and is due to the great and sudden change in rainfall intensity early in the storm.

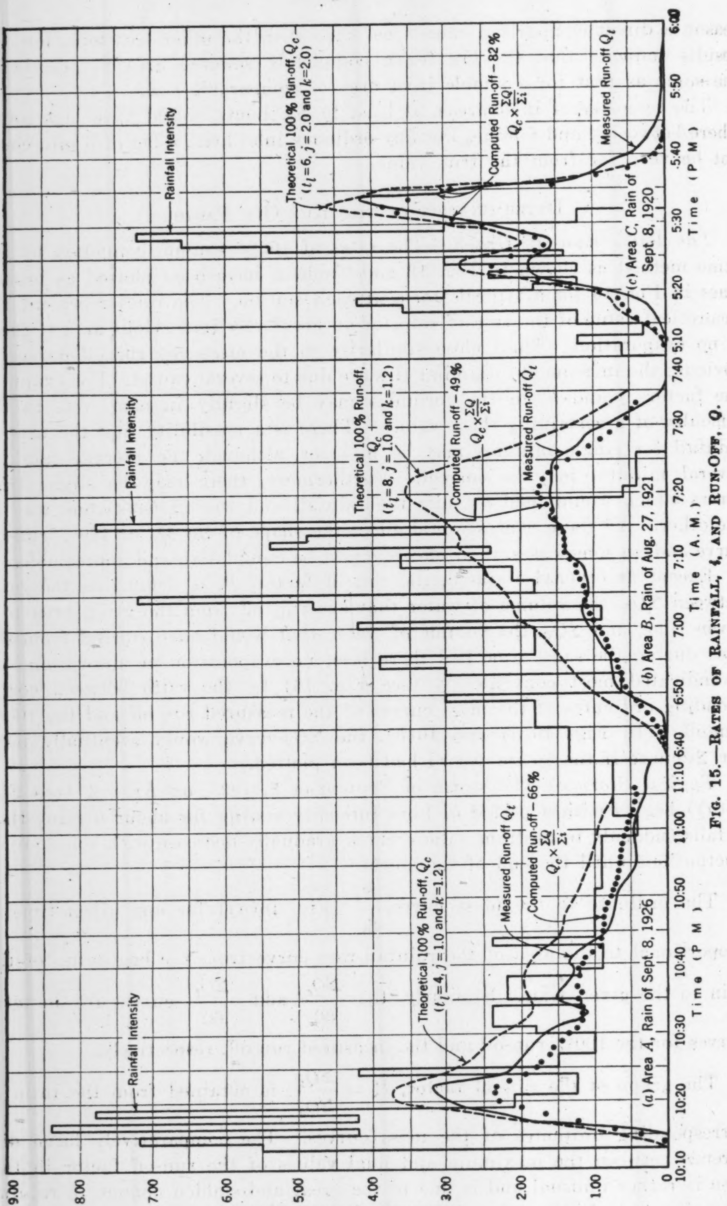

FIG. 15.—RATES OF RAINFALL, i, AND RUN-OFF, Q.

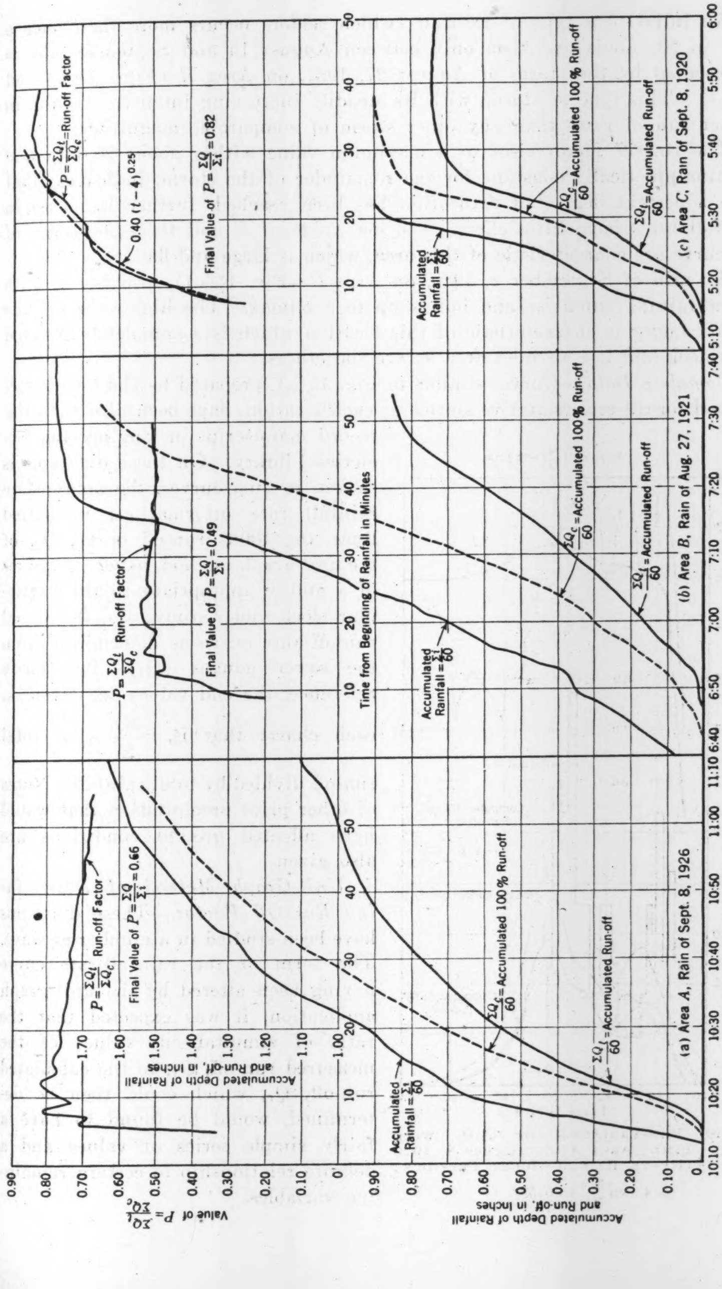

FIG. 16.—ACCUMULATED DEPTHS OF RAINFALL AND RUN-OFF AND VALUES OF P.

An interesting type of rainfall (which seldom occurs more than once a year in St. Louis and then only between August 15 and September 15) is represented by the storm of August 27, 1921, on Area *B* (Figs. 15(*b*) and 16(*b*)). This type of storm, with its steadily increasing intensity, results in higher run-off rates than any other storm of comparable magnitude.

The run-off factor rises to a maximum value within about 20 min and remains practically constant for the remainder of the storm, indicating that once a certain degree of saturation has been reached, further increases in rainfall rates have little effect. The low value of *P* and the smoothness of the curve are characteristic of this area, which is large and flat.

The rain of September 8, 1920, on Area *C* (Fig. 15(*c*)), also begins with a low rainfall intensity and builds up to a climax. The high value of the run-off factor is characteristic of this location which is a completely sewered city block and not an inlet area as are the others.

Complete Data.—Curves similar to Fig. 15(*a*), prepared by the unit-graph method for all representative storms at each location, have been filed with the record manuscript in Engineering Societies Library. On these diagrams is shown, in step curves, the appropriate rainfall rate information; in dotted lines, the 100% run-off curve, Q_c, of the unit-graph method, using the values of j and k appropriate to the particular block under study; and the actual run-off rate curve as determined from the sewer gauges (Q_t). For ready reference, the end values are given on each chart; that is, $\frac{\Sigma Q_t}{\Sigma i}$, or total run-off divided by total rainfall. Notes of other prior precipitation that would have affected ground conditions are also given.

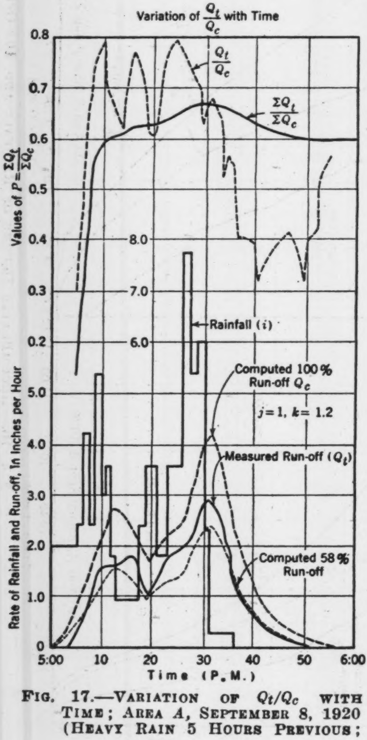

FIG. 17.—VARIATION OF Q_t/Q_c WITH TIME; AREA *A*, SEPTEMBER 8, 1920 (HEAVY RAIN 5 HOURS PREVIOUS; $= 4$ AND $\frac{\Sigma Q_t}{\Sigma i} = 0.58$).

Unit-Graph Method of Determining Run-Off Factor.—These diagrams have been studied in a number of ways. The form of the rainfall-rate curve having been altered by the unit-graph application, it was expected that the ratio of simultaneous values of the measured run-off, Q_t, to the calculated run-off, Q_c, which could then be determined, would be found to have a fairly simple series of values and a definite relationship to certain remaining variables.

Ratio of Instantaneous Values.—In Fig. 17, the rate ratio, $\frac{Q_t}{Q_c}$, is compared with the volumetric ratio, $\frac{\Sigma Q_t}{\Sigma Q_c}$. The former is much more irregular than the latter, due to the causes enumerated under the heading, "Determination of the Run-Off Factor: The 100% Run-Off Graph". It will be noted in Fig. 17 that when the slope of the run-off curve is zero (at the peaks and valleys) as at 5:13 P.M., 5:19 P.M., and 5:31 P.M., the value of $\frac{Q_t}{Q_c}$ is nearly the same as that of $\frac{\Sigma Q_t}{\Sigma Q_c}$. A practical comparison can be made by ignoring exact time relations and comparing Q_t with Q_c only for generally corresponding peak values.

The results of such a study of all the data are plotted as percentile curves on Fig. 18(*c*). The values cover a wide range and no method has been found to co-ordinate them to other variables. In Fig. 18(*b*), the values are separated in accordance with time of occurrence after the beginning of the rain, but without distinctive results. It seemed possible that more definitely characteristic values for each block might result from the use of average peak values of 5-min duration rather than extreme peak values. The rates thus obtained are shown on Fig. 18(*d*) and may be compared to Fig. 18(*c*).

There is a marked correlation between the ratio of these 5-min peak rates and the final value of the run-off factor, $\frac{\Sigma Q_t}{\Sigma i}$. Correlation diagrams, of which Fig. 19 is an example, indicate that the final value of $P_1 = \frac{\Sigma Q_t}{\Sigma i}$, when applied to the 100% run-off curve, will give a computed peak run-off which should approximate the true value, except for peaks occurring early in the storm. This final value of P_1 can be determined easily and accurately by the ratio of the total run-off to the total rainfall. It is not affected by time errors or by uncertainty as to values of j and k in the unit-graph formulas, as are the other ratios studied.

If each of the ordinates of the 100% run-off curve (for a given storm and location), as computed by means of the unit-graph formula, is multiplied by the final value of the run-off factor for the given storm, the resulting curve usually agrees fairly well with the measured run-off curve, as shown by the circled points in Fig. 15.

The agreement is better in the longer storms, and for the later parts of storms, especially if the maximum rainfall intensity occurs after 15 or 20 min of rainfall when the run-off factor curve has flattened out, as in Fig. 15(*b*). When the maximum rainfall intensity occurs early in the storm, the agreement is not so good (see Fig. 15(*a*)).

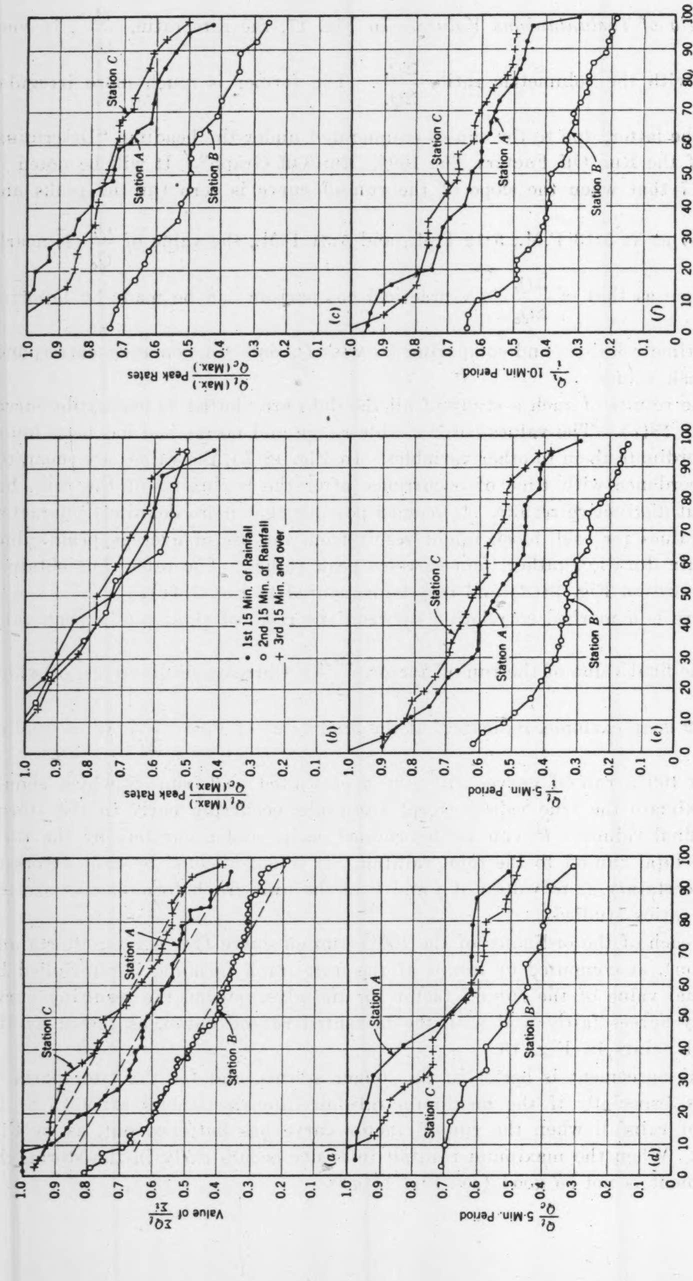

FIG. 18.—PERCENTILE CURVES OF RAINFALL-RUN-OFF RATIOS.

Relation of the Final Value of P to Other Variables.—In Fig. 20 an attempt is made to correlate the value of $P_1 = \frac{\Sigma Q_t}{\Sigma i}$ with the various factors indicated, and the only apparent correlation is in the case of the maximum run-off rate for a 5-min period. This indicates that high rates of run-off are more likely to be the result of a combination of relatively low rainfall rates and high run-off factors than the result of high rates of rainfall. Similar graphs for the other locations show similar results.

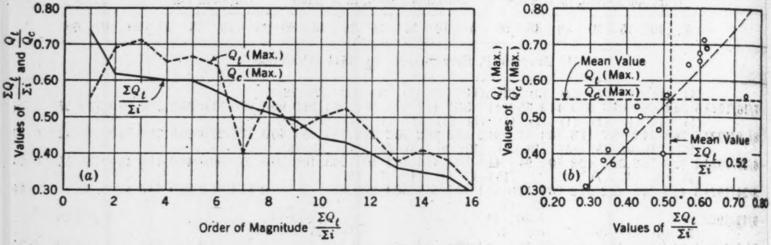

FIG. 19.—STATION *B*; CORRELATION DIAGRAM OF $\frac{\Sigma Q_t}{\Sigma i}$ AND $\frac{Q_{t\,(\text{max})}}{Q_{c\,(\text{max})}}$ FOR A 5-MINUTE DURATION PERIOD (BASED ON $j = 1$ AND $k = 1.2$).

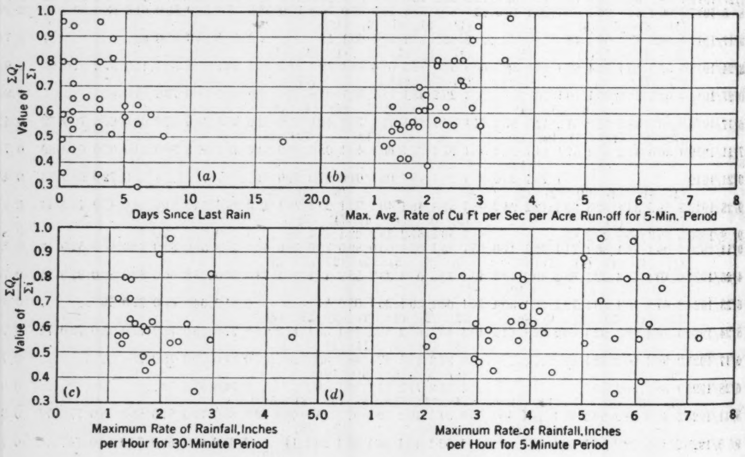

FIG. 20.—CORRELATION DIAGRAMS FOR $\frac{\Sigma Q_t}{\Sigma i}$; STATION *A*.

Ratio of Average Run-Off to Average Rainfall.—Pertinent information has been taken from the records and is given in Table 4. By means of these records it is possible to compare average rainfall rates with average run-off rates of the same duration, and also to compare these ratios with an end value of the run-off-to-rainfall ratio, P_1, as given in the last column.

In using Table 4, in the present case and in the frequency study that follows, it should be understood that the duration periods listed do not occur in the order listed for any particular storm; for example, at Station *A*, Table 4(*a*), for the rain of September 15, 1914, the entries under "20 minutes", for rainfall and run-off, which have numbers in parentheses of (11) and (17), are, respectively, the heaviest, average 20-min rainfall and the average rate of run-off for 20 min corresponding approximately with the particular rainfall occurrence. It is shown that the ratio of these average rates is 0.60 which corresponds closely to the ratio of the mean value for this storm. The numbers in parentheses correspond to the positions of these values in the frequency studies described subsequently.

Ratios of average run-off to average rainfall rates for 5-min duration and for 10-min duration have been taken from Table 4. As these values also vary over a wide range, they have been plotted as percentile curves, Fig. 18(*e*) and Fig. 18(*f*), and may be compared with other diagrams in Fig. 18. It should be noted that, while values on the various curves of Fig. 18 differ materially with the character of the ratio, the distribution of these values seems to follow about the same system for each diagram, as is indicated by a near parallelism of the lines. The close relationship of actual ratio values of curves in Fig. 18(*e*) and Fig. 18(*f*) with those of Fig. 18(*a*) is important.

GENERAL CONCLUSIONS TO PART I

Certain general conclusions, which the writers are inclined to draw from these exhibits are, as follows:

(1) The value of all run-off ratios studied for individual storms varies between wide limits at each observation station.

(2) The values of "P_1 (final)" have been plotted as percentile curves for each of the areas under study. This curve, given as Fig. 18(*a*), is similar to Fig. 18(*c*), Fig. 18(*d*), Fig. 18(*e*), and Fig. 18(*f*), and shows that for each of the areas studied, P varies quite widely from the mean; but, as with the other factors, $\left(\frac{Q_{t\,(\max)}}{Q_{c\,(\max)}}\right.$ for absolute peaks; $\frac{Q_t}{Q_c}$ for 5-min averages at peaks; and $\frac{Q_t}{i}$ for 5-min and 10-min averages at peaks$\left.\right)$, the trend of the three curves is surprisingly uniform in character, indicating that the variables which cause this divergence enter into the occurrence for each of the drainage areas in about the same way. Straight lines have been drawn in Fig. 18(*a*) to represent an average of the percentile points. These lines indicate that the run-off at Station *A* throughout the full range of values is likely to exceed that at Station *B* by about 20%, while the rate for Station *C* will exceed that at Station *A* by about 10 per cent.

(3) For a given drainage area, the run-off factor, P, seems to be affected by the season of the year, general climatic conditions, previous precipitation, etc., but no co-ordination has been determined.

(4) No evidence of general correlation has been found between the "final value" of the factor, $P_1 = \frac{\Sigma Q_t}{\Sigma i}$, for individual storms, and the rainfall characteristics of the storms (such as maximum i or mean i). However, the variation of the run-off factor during the progress of a storm seems to depend, to some extent, upon the variation of the rainfall intensity. The effect is not pronounced except in extreme cases, such as double or multiple rains, when the rainfall intensity falls to low values for considerable periods between the peaks.

(5) The ratio, $\frac{\Sigma Q_t}{\Sigma i}$, or total measured volume of run-off to total measured volume of rainfall, has been found to have a close correlation with the ratio, $\frac{Q_{t\,(\max)}}{Q_{c\,(\max)}}$, based on 5-min duration periods (see Fig. 19, for example). The ratio, $\frac{\Sigma Q_t}{\Sigma i}$, can be found conveniently with great accuracy, and provides the best information as to the general relation between rainfall and consequent run-off rates for any given storm.

(6) No doubt, the value of the run-off factor, P, is greatly affected by the nature of the soil, but the local records can throw no light on this phase of the subject, since the soil is the same yellow clay at each of the observation stations. The sprinkling experiments were undertaken to fix the values given in this paper to a definite soil condition. (See Table 8.)

(7) The wide variation in the "final values" of P at each of the sites must be attributed to combinations of three variables: (*a*) Condition of the soil; (*b*) condition attributed to coverage; and (*c*) character of the distribution of the rainfall rates:

(*a*) Variation in Soil Condition. — This variation probably is closely similar to that of the soil-moisture content, and accordingly is affected by previous precipitation and by the seasons of the year.

(*b*) Variation in Condition of Coverage.—The effect of the character of the turf on the lawns and of the foliage on trees and shrubbery, also would appear to have some relation to the season of the year.

(*c*) Character of the Distribution of the Rainfall Rates.—The final value, P (which is the ratio of total run-off to total rainfall), is not subjected to the effect of distribution which the unit-graph study brings to the values of $\frac{Q_t}{Q_c}$ during the rainfall. Accordingly, it will vary seriously with the manner in which precipitation departs, in one way or another, from the condition of uniform intensity.

SUMMARY OF CONCLUSIONS TO PART I

In Part I, studies have been made of the run-off factor under the unit-graph method in three forms: First, as the ratio, $\frac{Q_t}{Q_c}$, or instantaneous ratios; second, as the ratio, $\frac{Q_t}{Q_c}$, for generally coincident peak values; and, third, as $P = \frac{\Sigma Q_t}{\Sigma Q_c}$, a moving ratio of mass values.

Studies have been made of the direct relation between run-off and rainfall: First, as ratios of average run-off rates to average rainfall rates for the same duration; and, second, as the final value, $P_1 = \frac{\Sigma Q_t}{\Sigma i}$. These experimentally determined ratios have been found to vary over a wide range, and a satisfactory correlation to other variables has not been found.

The unit-graph process is probably the best yet developed for analyzing rainfall and run-off data of the kind presented in this paper. If some modification of it can be applied generally to run-off data hereafter available, it will be possible to study the remaining variables entering into the relationship between rainfall and run-off in a much simpler form than heretofore has been undertaken.

Further prosecution of the investigation undertaken herein, might appear to involve a series of studies. First, the unit-graph method would yield a factor similar to the coefficient of retardation, representing the ratios between $Q_{c(max)}$ as used in this section, and average rainfall intensity for particular duration periods classified as to frequency of occurrence. The second series would involve a determination of the values of $\frac{Q_t}{Q_c}$, a run-off factor, as has been attempted, with the proper relation to frequency of occurrence.

If such information were satisfactorily developed, the run-off rates would be determined by applying to average rainfall intensity of the proper frequency and duration, a coefficient of retardation, thus reducing it to a 100% run-off rate, and, thereafter, applying the value of $\frac{Q_t}{Q_c}$ to reduce to actual run-off rates.

Such an undertaking, however, becomes involved in numerous complications. It appears that the same results could be secured by a simpler means, although probably in a less scientific manner, if the information on rainfall and on run-off was made the subject of frequency-of-occurrence studies as if the two phenomena were independent.

PART II.—FREQUENCY STUDY OF RUN-OFF RATES

In Part II, run-off is considered as an independent phenomenon, and a frequency study is made of the average rates of run-off for various duration periods at each observation station, in order to determine the answer to the question, "How often in a given number of years will a given inlet area discharge storm water at a given rate for a given duration period?"

Frequency is expressed in years and has reference to the period of time during which an event of given magnitude will probably be equalled or exceeded one time. Table 4 shows the basic data used in the frequency study. A period of years was chosen for each location such that a continuous series of the best records for that location was available. At Station A, the nineteen years, from 1914 to 1932, inclusive; at Station C, the twelve years, from 1916 to 1927, inclusive; at Station B, the sixteen years, from 1914 to 1929, inclusive; and at the United States Weather Bureau Station, the twenty-two years, from 1907 to 1930, inclusive, were chosen as the most representative. (On September 29, 1925, the rain gauge at Station B was taken out of service. After that date, rainfall rates for this location were obtained by interpolation from three near-by gauges.)

These series although shorter than might be desired, are longer than the usually accepted minimum of about ten years. At each station all storms having significant average run-off rates (about 1.0 cu ft per sec per acre, or more) for the duration periods represented in Table 4, are listed in chronological order.

Under the heading, "Rainfall", in Table 4, is listed the highest average rate of rainfall, observed during the storm in question, for the various duration periods. Under the heading, "Run-Off," is listed the highest average rate of run-off observed during the storm in question, for the various duration periods of run-off.

The numbers in parentheses, shown with the rates, represent the order in magnitude of that rate for the duration period in which it is shown. For example, referring to Table 4(a), during the storm of September 15, 1914, as observed at Station A, the highest average rainfall rate for a period of 20 min is 2.47 in. per hr, and this rate for this duration period has been exceeded ten times in the nineteen years represented in the table. The highest average run-off rate, for a duration period of 20 min, is 1.47 cu ft per sec per acre, and this rate has been exceeded sixteen times during the nineteen years. Where no numbers in parentheses are shown, the rate has been exceeded more times than the number of years represented in the series.

The columns headed, $\frac{\text{Run-Off}}{\text{Rainfall}}$ (Table 4), contain the ratios of the run-off rates to the rainfall rates, as shown in the preceding columns. Of course, the duration periods shown for run-off rates are not identical in absolute time with the corresponding duration periods shown for rainfall rates, the difference being due to the lag. In one or two instances, the duration periods compared belong to entirely different phases of the rain.

The column headed, $\frac{\Sigma Q}{\Sigma i}$ (Table 4), shows the ratio of the total run-off to the total rainfall for the entire duration of the storm in question. This information is not given for a few storms of long duration where the rates are insignificant for most of the time, only the peak values being investigated.

Table 5, being taken from the records of the U. S. Weather Bureau, shows rainfall rates only. The information on which the frequency series was determined is complete and consecutive with the exception of one storm, that

December 13, 1920	4.60 (14)	3.12	2.32	....	....	....	....

of August 8, 1923, for Station *C*, and is accurate within the limitations of the instruments used. The years, 1918 and 1932, are not represented in Table 4(*a*) for Station *A*, nor are the years, 1922 and 1929, in Table 4(*b*) for Station *B*, as no rains of sufficient magnitude occurred in these years to warrant inclusion. Several storms were included for which the data were open to suspicion on the grounds of non-conformity, such as that of September 12, 1925, at Station *A*, and the small rains showing more than 100% run-off, but for which no definite defect in the record could be found.

Derivation of Series.—A frequency series was made up for each vertical column under the headings, "Rainfall" and "Run-Off", in Table 4. The rates taken from each column were arranged in the order of magnitude beginning with the highest. Since the class of storms that occur, on an average, more than once each year are of little or no interest in design, the number of terms in each series was arbitrarily limited to the number of years represented in Table 4 from which it was taken. This makes the number of events equal to the number of years in the series, facilitating the computation of the time frequency.

The frequency percentages for each series were computed from the formula[4]:

$$F = \frac{2\,m - 1}{2\,n} \qquad \text{..........................} (5)$$

---

[4] "Method of Least Squares", by Mansfield Merriman, M. Am. Soc. C. E.

in which, F = percentage of frequency; m = ordinal number of the item in the series (the maximum being No. 1); and, n = number of items in the series.

The rates of rainfall and run-off as selected for the various series were plotted against the corresponding frequency percentages on logarithmic probability paper (Fig. 21). Since direct comparisons were to be made between the different series, it was decided to derive the curves through the plotted points by computation, using statistical rather than graphical methods, in order to eliminate the personal equation and assure that each series would receive exactly the same treatment.

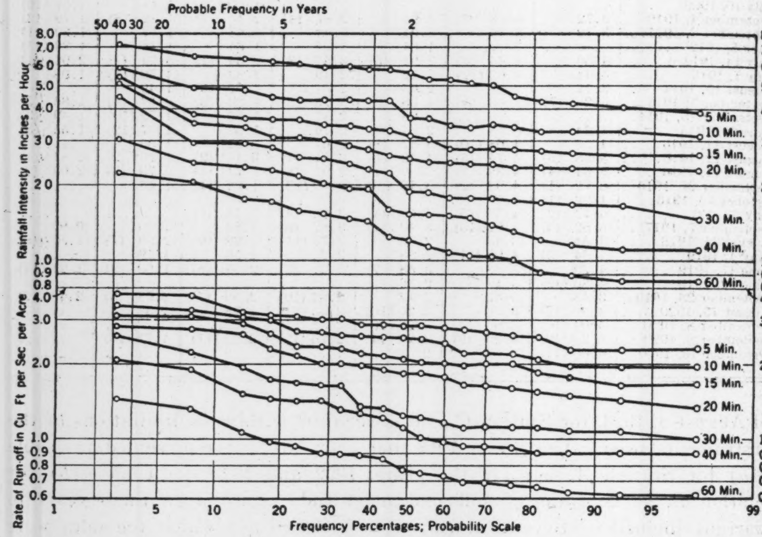

Fig. 21.—Station *A*. Rainfall and Run-Off Frequency Series, 1914 to 1932, Inclusive; Rate Frequency Curves.

The method used in computing the points on the smooth curves in Fig. 21 consists of calculating: First, the mean value of the terms in each series; and, then, the coefficients of variation and skew for the series. Knowing the value of these coefficients, the co-ordinates of points on the skew frequency curve were calculated from the information given in the table[5] of skew curve factors by H. Alden Foster, M. Am. Soc. C. E. Details of these computations and complete sets of curves are filed with the record manuscript in Engineering Societies Library.

The curves, such as those shown in Fig. 21, indicate the probable frequency of occurrence of given rates of rainfall and run-off, expressed as a percentage of the total number of events of the same class in a given array;

(c) Station C, Ewing and Washington Avenues

FIG. 22.—RELATION OF RATES OF RUN-OFF AND RAINFALL TO DURATION OF THESE RATES.

for example, a rainfall or run-off rate having an event frequency of 20%, as shown by the graph, will probably be equalled or exceeded once in five years.

Transposing the co-ordinate axes and plotting the data given by the curves of the type of Fig. 21, a series of curves are obtained which show the relation of the rates of run-off and rainfall to the duration of these rates for frequencies of 50, 40, 30, 20, 10, 5, and 2 years. These curves (Fig. 22) correspond to the familiar "rainfall-intensity" curve.

Correspondence Between Series.—There is no causal connection between corresponding points on the rainfall and the run-off curves for a given frequency. Such points do not represent actual storms, but only rates having the same probable frequency. The curves represent variations in concurrent, but not necessarily completely dependent, phenomena.

Fig. 22 shows also the ratios between corresponding rainfall and run-off rates for various frequencies taken from these rate-duration curves. The usefulness of these ratios lies in the fact that the data from several observation stations may be combined to provide a rainfall frequency series of greater length and possessing greater scope and accuracy than is possible in the case of the local rainfall and run-off frequency series.

Transformation to Long-Time Series.—The ratios between corresponding rainfall and run-off rates, as shown by the local rate-duration curves, reflect the local conditions that affect the rainfall-run-off relations at the station in question. Therefore, when these ratios are applied to rainfall rates given by the long-term rainfall frequency series, the resulting rate-duration curves should show the most probable values for run-off rates for various frequencies and duration periods at each station.

Another advantage of this method is that it takes into account the position factor of rainfall rates and its effect on run-off rates. A high rainfall rate at the beginning of a storm, may result in an insignificant rate of run-off while a much lower rate of rainfall of the same duration, occurring late in a storm, may result in a relatively high rate of run-off. In the long-term rainfall frequency series, all types of storms are included, and the position factor of the various rainfall rates is taken into account (at least indirectly) with the relative frequency of the various types of storms.

A long-time series, comprising 47 station-yr, may be obtained by combining the rainfall records of the three observation stations; but two of the stations (Stations *A* and *B*), are quite close together, while the third (Station *C*), is about four miles away (see Fig. 1). Since the U. S. Weather Bureau Station is fairly close to Station *C*, this fault may be minimized by combining the records from these four stations, thus obtaining a 61-station-yr series. It will be seen from Tables 1 to 5 that few critical storms are common to all four stations, and that the record at no one of the stations having a length of from 12 to 17 yr can be truly representative of the rainfall probabilities for the short storms of the St. Louis region. This 61-station-yr series, shown in Fig. 23(*b*), has been adopted as the basis of the final frequency study. It could have been improved somewhat by using all the rain-gauge sta-

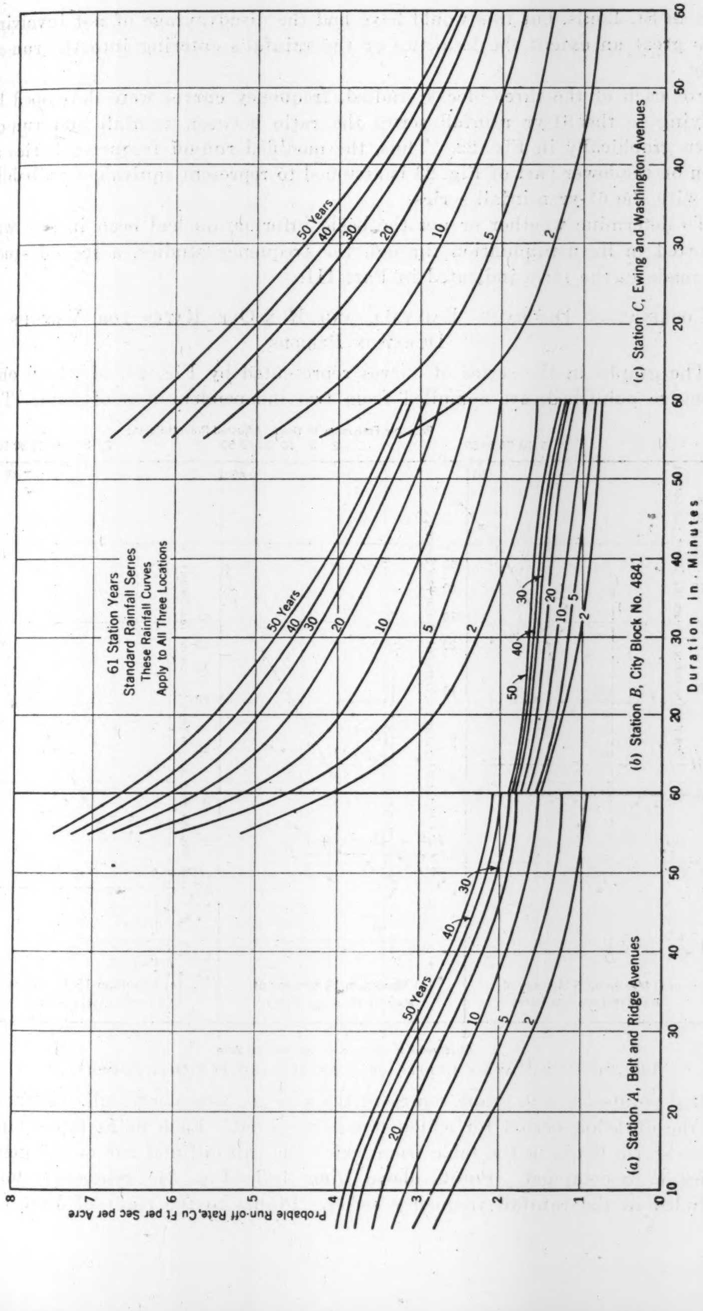

FIG. 23.—ADJUSTED RUN-OFF RATE CURVES BASED ON STANDARD RAINFALL SERIES.

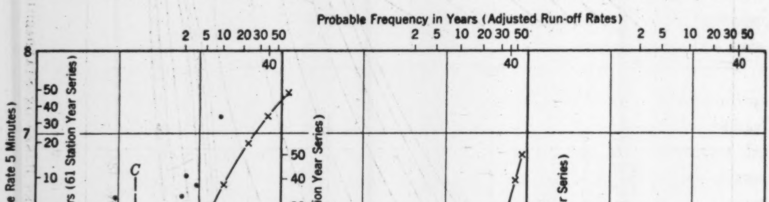
tions in St. Louis, but this would have had the disadvantage of not involving to so great an extent the localities or the rainfalls entering into the run-off study.

For each of the three blocks studied, frequency curves were developed by applying to the 61-yr rainfall series the ratio between rainfall and run-off shown graphically in Fig. 22. Thus, the modified run-off frequency series as given on the lower part of Fig. 23 is assumed to represent equivalent probabilities with the 61-yr rainfall series.

To determine whether or not the basic information had been in any way distorted in its manipulation through the frequency studies, a second study was made in the form indicated in Part III.

Correlation Diagrams—Rainfall and Run-Off Rates for Various Duration Periods

The graphs in the series of curves represented by Fig. 24, of which only three are published, are compiled from two independent sets of data. The plotted points on each graph represent the average rate of rainfall and run-off for the duration period for which it was prepared. Each point represents a single storm listed in the table from which the rainfall and run-off frequency series were compiled. Points above Line *A-B* (Fig. 24) represent storms included in the rainfall frequency series. Points to the right of Line *C-D*



(a) Maximum 5 Minutes of Rainfall (Average Rate)

(b) Maximum 10 Minutes of Rainfall (Average Rate)

(c) Maximum 15 Minutes of Rainfall (Average Rate)

FIG. 24.—CORRELATION CURVES OF RAINFALL AND RUN-OFF, STATION *A*.

represent storms included in the run-off frequency series. Lines *E-F* and *H-I* define the mean values of the rainfall and run-off rates in relation to the vertical and horizontal axes, respectively, thus establishing Point *G* as the center of gravity of all the points.

Referring to Table 4(*a*), it is seen that for the first storm listed at Station *A* (September 15, 1914), the maximum average rainfall rate for a 5-min period is 3.12 in. per hr, and the maximum average run-off rate for the same period is 1.89 cu ft per sec per acre. The point representing this storm, therefore, is located from these co-ordinate values on Fig. 24(*a*).

The frequency scales shown on the rainfall and run-off rate axes are taken from the rate-duration curves (see Figs. 23(*a*) and 23(*b*)) where it is found that the rainfall rate having a probable frequency of 2 yr (for 5-min duration period) is 5.10 in. per hr, while the corresponding run-off rate is 2.85 cu ft per sec per acre, etc., for each frequency.

The points designated by crosses in Fig. 24, and connected by solid lines, are plotted opposite corresponding frequencies as shown on the rainfall and run-off axes on the right-hand top margins of each chart. These points do not represent actual storms, but only abstract rainfall and run-off rates having the same probable frequency, in years, as determined by the rate-frequency graphs for Station *A*. The relation of this line to the points shows that, although points on the frequency curve were extrapolated beyond the observed data, the general trend of the ratio of run-off rate to rainfall rate as observed in the original data has been preserved in the extrapolated values.

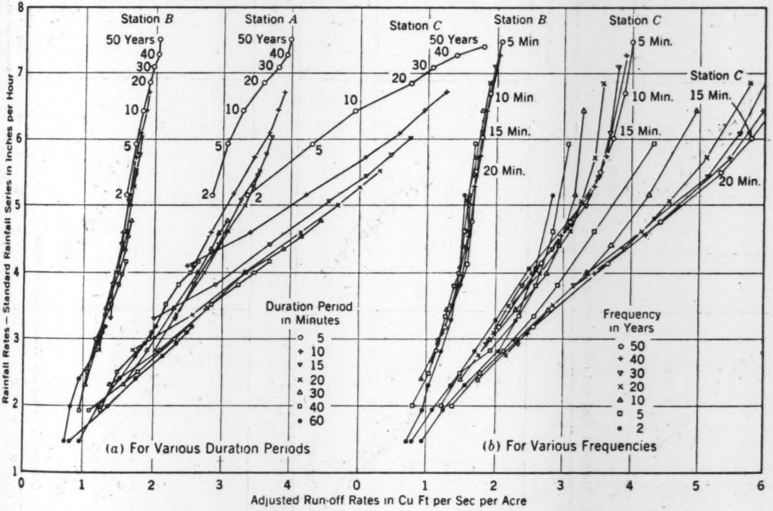


FIG. 25.—RELATION BETWEEN RAINFALL AND RUN-OFF RATES (SEE TABLE 6).

From this series of diagrams two composite charts (Fig. 25 and Table 6) were compiled, which gave identical information as to the plotted points,

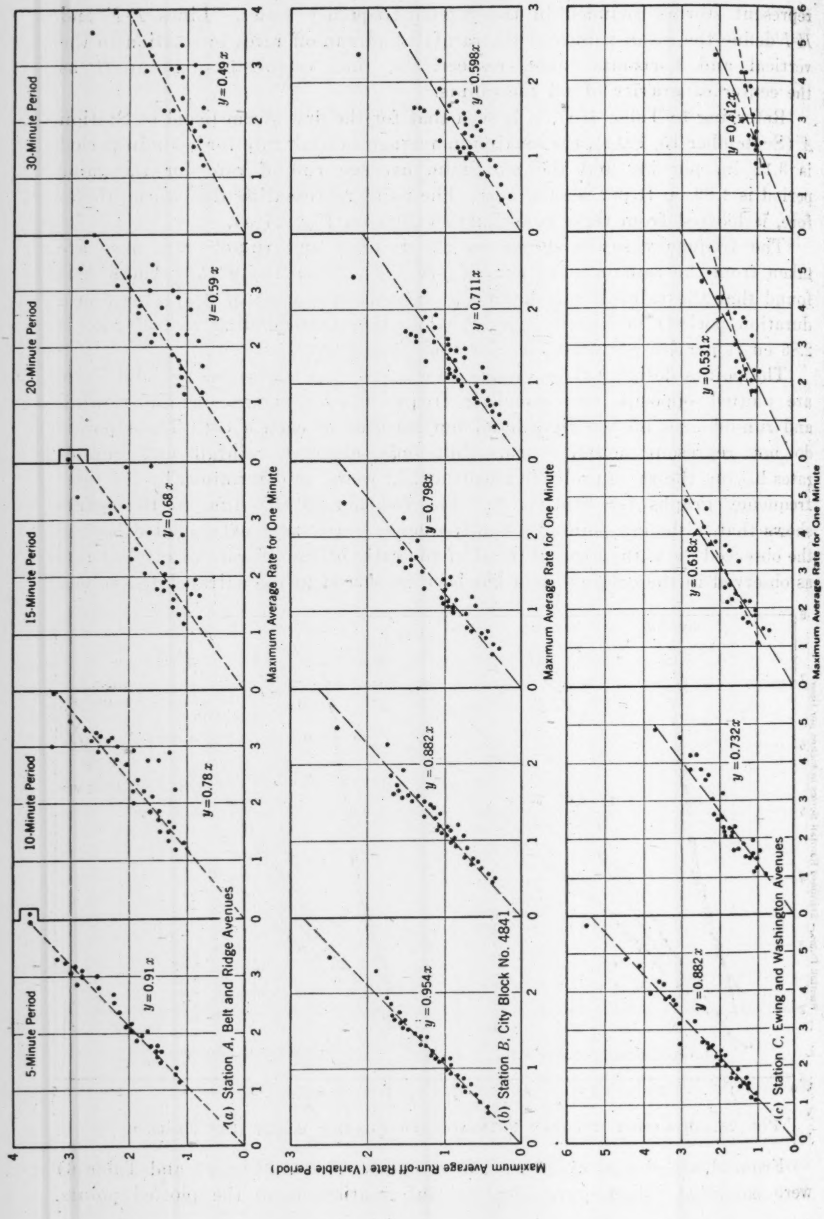

FIG. 26.—CORRELATION DIAGRAMS; MAXIMUM AVERAGE RUN-OFF RATES FOR VARIOUS DURATION PERIODS COMPARED WITH MAXIMUM AVERAGE RATE FOR 1 MINUTE (UNITS IN CUBIC FEET PER SECOND PER ACRE)

and differed only in the connecting lines shown between the points. They involve essentially the same information that is presented in Fig. 23. Each of the diagrams offers different aspects.

TABLE 6.—RELATION BETWEEN RAINFALL AND RUN-OFF RATES FOR VARIOUS DURATION PERIODS AND FREQUENCIES (SEE FIG. 25)

Description	Station *A*	Station *B*	Station *C*
Tributary area, in acres	2.25	3.25	4.33
Percentage of area, impervious	50	29	72
Percentage of area, pervious	50	71	28
Average slope (percentages)	3	0.7	2.0

Figs. 23 and 25 contain the results of the run-off frequency study. However, in Fig. 26, this material has been set up to present one other relationship. These diagrams were prepared by comparing the average run-off rates for particular duration periods, as, for example, 5 min and 10 min, with the maximum average run-off rate for 1 min for the same storm. The information as to the average 5-min and 10-min rates was taken from Table 4. The tabulated data for the 1-min rate are not presented, but they were taken directly from the hydrographs. The relationships indicated in these diagrams, as summarized on Fig. 27, are surprisingly consistent. It should be noted that the relationship for Station *C* (Ewing and Washington Avenues) for the 20, 25, and 30-min periods, does not seem to follow a slope line through the origin as clearly as is the case for other curves, and the line drawn is a mean used only for the purpose of preparing the curve on Fig. 27. While it is not expected that the relations given by the curves can be of immediate use in connection with sewer design, they are interesting and should be of real value to the hydrologist.

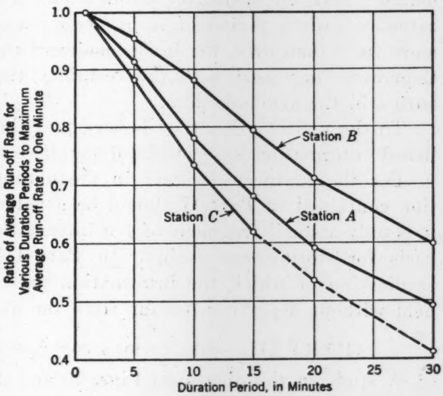

FIG. 27.

The run-off values shown on Fig. 22(*a*) for Station *A* and those for Station *B* in Fig. 22(*b*), seem to fit into a logical conception of the effect of topography and surface condition on run-off rates. The curve for Station *C* (Fig. 22(*c*)) giving the result for an entire city block, including many sub-areas such as roofs and yards that drain directly to the sewer, is not strictly comparable to the information for the other two blocks. The very high run-off rates shown in this case were surprising to the writers, even in view of their familiarity with conditions.

Figs. 22(*a*) and 22(*b*), show that for the two smaller locations, the greatest ratio between run-off and rainfall occurs for the lighter and more frequent rains; for Area *C* the reverse is true. Tracing the reversal phase back into the primary data, it is noted that the corresponding rainfall and run-off curves for Area *C* diverge to the right, whereas for the other sites these curves approach each other for the longer time.

This means that the range of run-off rates at Station *C* is greater than the range of rainfall rates; that is, the drainage system at Station *C* is more sensitive to changes in rainfall rates than the systems at the other locations, due probably to the manner of collecting the water. The mean velocity from points on Area *C* is greater than that from points on Area *A* at the same distance from the point of measurement.

Fig. 25 brings out in an interesting manner the fact that the run-off characteristics of the three sites are quite similar for the light rainfalls, and it is only in the field of the rarer occurrences and greater intensities that the marked differences appear. For Station *B*, the relationship of rainfall and run-off is affected, to a relatively small degree, by variation in duration or in frequency; for Station *A*, more important differences appear on this account; and, for Station *C*, the effects are distinctive.

Conclusions to Part II

At various times during the period, 1924 to 1934, the writers and their associates have attempted to organize the information given herein in a manner that would justify publication. The present effort at analysis has extended over a period of nearly two years, and the writers now recognize, more fully than ever, the inadequacies of the results secured. They are more than ever impressed with the certainty that much of importance still lies buried in the available data.

To the hydrologists, they believe that they are presenting hitherto unpublished information susceptible of detailed study and interpretation.

For the engineer designer in the municipal drainage field, the information contained in Part II should be a valuable guide to judgment, although it is only a small fragment of the information desirable for reaching a sound basis for storm-sewer design. In Part III a method is suggested in the application of which the information presented will be usable in a broader field without departing too far from the available facts and figures.

PART III.—Suggestions for Application to Sewer Design

A study of the diagrams, Figs. 23 and 25, brings out the following crude relationships:

(1) For flat areas of relatively low percentage of imperviousness (such as, Area *B*), the relation between rainfall and run-off of equal probability does not vary greatly with frequencies or durations; the average ratio is slightly less than 0.4

(2) For steeper and less permeable areas (such as Area *A*), the correlation is fairly uniform except for the shorter 5-min rains, and the average ratio is about 0.65.

(3) For the closely built-up block (such as Area *C*), the correlation is not so simple, and the average values are greater than 0.8.

(4) Table 7 gives in round figures the principal characteristics of the three test sections.

TABLE 7.—PRINCIPAL CHARACTERISTICS OF AREAS STUDIED

Area (see Fig. 16) (1)	Average slope (percentages) (2)	Percentage of area, impervious (3)	General average ratio of run-off rates to rainfall rates (4)
B................	0.7	30	0.4
A................	3.0	50	0.65
C................	2.0	72	0.8

(5) With only three sites sufficient sets of information are not available to permit of a proper attempt to isolate the effect on the run-off ratio (Column (4) Table 7), of the variable in Column (2), from that of the variable in Column (3). It has been interesting, however, to attempt to set up a series of ratios for the pervious and impervious areas, found by "cut-and-try", that would develop the actual run-off rates given in the final diagrams.

A typical, although incomplete, study of this type for a 15-yr rain is presented in Table 8.

TABLE 8.—EFFECT OF GROUND SURFACE SLOPE ON THE RUN-OFF RATIO (COLUMN (4), TABLE 7) (FIFTEEN-YEAR STORM DATA)

Item No.	Area (see Figs. 2, 3, and 4)	PERCENTAGES OF AREA:		Percentage of run-off, *P*	Rainfall rate, in inches per hour	RUN-OFF, IN UNITS, INCHES PER HOUR

10...	*A*	....	50	40	3.70	0.74		
11...	*C*	72	....	90	3.70	2.40	3.02	3.10
12...	*C*	....	28	60	3.70	0.62		
				(*c*) DURATION PERIOD, 20 MINUTES				
13...	*B*	30	....	75	4.3	0.97	1.57	1.50
14...	*B*	....	70	20	4.3	0.60		
15...	*A*	50	....	88	4.3	1.89	2.64	2.90
16...	*A*	....	50	35	4.3	0.75		
17...	*C*	72	....	88	4.3	2.72	3.39	3.70
18...	*C*	....	28	56	4.3	0.67		

Computation Table 8 is not offered as a good solution of this problem; the writers merely wish to leave it to practical sewer designers for further analysis. Note that the "pervious" surface on Areas *A* and *B* (Fig. 5(*a*)) is turf, and that on Area *C* (Fig. 5(*b*)), it is small areas of packed soil.

As an indication of the effect of slope on run-off from sodded areas such as lawns, a number of diagrams were drawn of the St. Louis sprinkling experiments of 1923 (filed with the record manuscript in Engineering Societies Library). Three runs each from Plot *B* (5% slope) and from Plot *C* (0.8% slope) are analyzed, using rainfall rates of 2½ in. (adjusted), and comparing run-off rates that seem to prevail for some time (30 to 40 min) after run-off begins.

A rough comparison of values in Table 9, in the absence of pondage, indicates that the run-off from good slopes may be 15% greater than from practically flat areas. Measured run-off rates from Area *A* (3% slope) are nearly two-thirds greater than from Area *B* (0.7% slope), but the former is also less pervious, while pondage is prevalent in the latter. These data indicate a difference in the water lost—that is, in water not appearing as run-off—of 11% as between the 0.5% slope and the 5% slope.

TABLE 9.—EFFECT OF SLOPE ON RUN-OFF FROM SODDED AREAS

(*a*) PLOT *B*, 5% SLOPE						(*b*) PLOT *C*, 0.8% SLOPE					
Date	Ground conditions	Run-Off Rate, in Units:		Loss		Date	Ground conditions	Run-Off Rate, in Units:		Loss	
		Each observation	Average	Rate, in units	Percentage			Each observation	Average	Rate, in units	Percentage
May 9, 1923	Damp	2.00	1.93	0.57	20	Aug. 31, 1923	Damp	1.90	1.73	0.77	31
July 26, 1923	Dry	2.00				May 12, 1923	Dry	1.70			
Aug. 1, 1923	Wet	1.80				July 26, 1923	Damp	1.60			

Within narrow limits, these values may be used to adjust, for slope, the coefficients in Table 8; for example, if the city block had all the characteristics of Area *A*, except that the slope is 2% instead of 3%, the coefficient of the pervious portion could be reduced from 0.45 to about 0.39. This should probably be charged against a slightly higher rate than the nominal run-off, to allow for water spilling from yard walks on to lawns, a condition equivalent to an increased rainfall rate on the lawns. In this instance, the revised run-off might be taken as 50% of 39% of 3 in. as compared with 50% of 45% of 3 in., a reduction in average run-off rate for the block from 1.89 to 1.80. Of course, modifications of this kind cannot be used too extensively or too far from the field of original figures. If used for very flat areas, such as Area *B*, allowance should be made for the effect of increased pondage.

The effect of soil characteristics on run-off rates, and on the probable frequency of occurrences of specific run-off rates, limits the direct value of the presented data to St. Louis conditions, or where all conditions are substantially equivalent to those of one of the blocks studied. The results can be modified. however, to be of value for other localities.

The volumetric ratio has proved to be the best index to the varying value of the ratio between run-off rates and rainfall rates during the progress of a storm. It provides a convenient means of comparison between different types of inlet areas (see percentile curves, Fig. 18(*a*)). It has given remarkably uniform and consistent results when applied to the sprinkling experiments of St. Louis and Dallas, Tex. (Complete supporting data are filed with the record manuscript, in Engineering Societies Library.) This ratio is suggested for use in adjusting run-off rates to other soil types, using the Dallas information, which is given in part in Fig. 28 and in Tables 10 and 11, as an example.

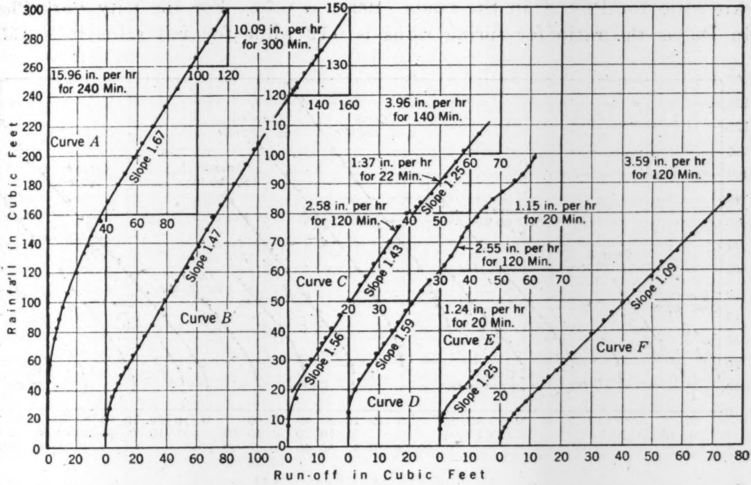

FIG. 28.—VOLUMETRIC RATIOS OF RAINFALL TO RUN-OFF, 1931–1932; SPRINKLING EXPERIMENTS, CITY PARK, DALLAS, TEX. (SEE TABLE 11).

TABLE 10.—VOLUMETRIC RATIOS OF RUN-OFF TO RAINFALL; SPRINKLING EXPERIMENTS (NO PONDAGE)

Item No.	(*a*) EXPERIMENTS AT ST. LOUIS, MO.					(*b*) EXPERIMENTS AT DALLAS, TEX.				
	Plot	Year	Soil condition	Ratio		Plot*	Season	Soil condition	Ratio

* Plot *A* is Southern Methodist Univ.; Plot *B* = City Park Plot; and, Plot *C* = Exall Park Plot.

Plot *B*, Fig. 29, is comparable with the City Park Plot in Dallas, in that the slopes are about the same and both are sodded; and a direct comparison

TABLE 11.—OBSERVATIONS TO DETERMINE VOLUMETRIC RATIOS OF RAINFALL TO RUN-OFF; SPRINKLING EXPERIMENTS, CITY PARK, DALLAS, TEXAS (SEE FIG. 28).

Curve	Date	Time	Remarks
A	November 7, 1931....	9:30 A.M...	Dry; heavy dew on a good stand of thick, heavy, green grass.
B	November 9, 1931....	9:00 A.M...	Fair and cool; light wind; damp.
C	November 10, 1931....	8:30 A.M...	Cloudy; wet.
D	March 1, 1932........	12:30 P.M...	Cloudy; warm.
E	March 2, 1932........	....	Cloudy; cool; ground soft and damp; heavy dew.
F	March 5, 1923........	....	Ground saturated and frozen; fair, cold, and windy.

of the soil conditions on the two plots may be made by comparing their volumetric ratios between run-off and rainfall. In Table 10 it is seen that this ratio for Plot *A* in St. Louis (1923) is 0.76. For the City Park Plot in Dallas the ratio for spring rains is 0.72 while for fall rains it is 0.57.

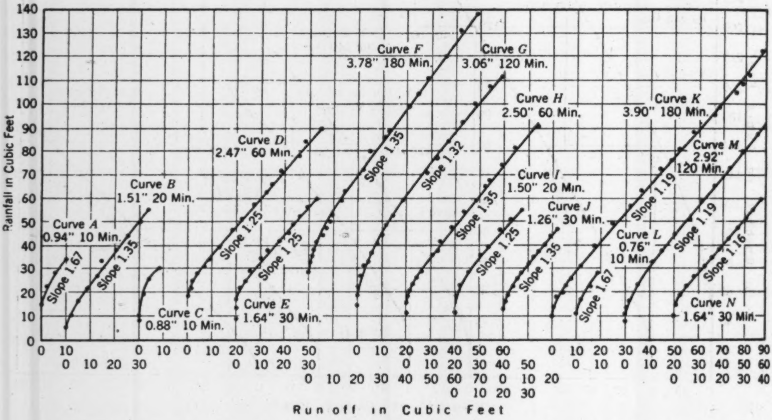

FIG. 29.—VOLUMETRIC RATIOS OF RAINFALL TO RUN-OFF, 1923; SPRINKLING EXPERIMENTS, PLOT *B* (SODDED), ST. LOUIS, MO. (SLOPE, 5.1 PER CENT).

Thus, the first important difference in conditions at the two localities becomes apparent; the correlation diagram, Fig. 30, shows that there is no marked difference in this ratio between spring and fall rains at St. Louis.

It is evident that if the Dallas plot is representative of general soil conditions in that city, the St. Louis run-off curves, Fig. 23 (ignoring frequencies, for Station *A* (Belt and Ridge Avenues), for example), could be modified to find the probable run-off from similar blocks in Dallas for given intensities and duration periods. For winter and spring rains at Dallas, little or no adjustment of St. Louis ratios would be necessary since the corresponding ratios are practically equal. For summer and fall rains, rates derived from the St. Louis data would need to be adjusted in accordance with the relative losses shown in the sprinkling experiments. For St. Louis, the water losses through surface film and absorption are given as $\frac{100 - 76}{100} = 24$ per cent. For Dallas, the corresponding loss is $\frac{100 - 57}{100}$ = 43 per cent. The difference in water loss, therefore, is 19% of the rainfall. If all other conditions are equal, except that it is desired to alter Item No. 4, Table 8, for summer and fall soil conditions at Dallas, the computation for the pervious portion (Table 8, Item No. 4, Column (4)) would involve the reduction of the factor 45% by 19, or to 26%, and this, again, should probably be chargeable against a Dallas intensity of a frequency equivalent of the St. Louis rainfall rate of 3 in. per hr.

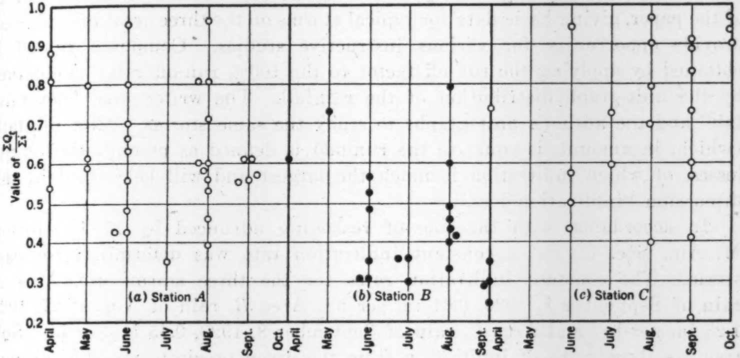

FIG 30.—CORRELATION DIAGRAMS; SEASONAL VARIATION OF VALUE $\frac{\Sigma Q_t}{\Sigma i}$. ST. LOUIS EXPERIMENTS

In this particular case, it would probably be advisable to draw two independent rainfall frequency curves for Dallas, one for winter and spring rains and one for summer and fall rains. For a given design frequency, it might be that for some duration periods the spring curve would govern, while for other periods the fall curves might be indicated.

CONCLUSIONS TO PART III

In general, it is suggested that the data presented may be made useful in localities other than St. Louis, by well-considered modifications in four respects:

(*a*) An adjustment of the run-off curves of Fig. 23 in the direction and proportion that rainfall curves of the new locality may bear to the 61-yr rainfall curve given in Fig. 23(*b*).

(*b*) With regard to varying percentages of impervious area, as suggested in Table 8.

(*c*) For slight differences of slope as outlined in Table 7.

(*d*) For other soil types as in the last paragraph.

Somewhat better information would be made available through such modifications than has generally been the case. It is highly desirable that additional tests and repetitions of these experiments be conducted in other localities in the near future.

DISCUSSION

Franklin F. Snyder,[6] Jun. Am. Soc C. E. (by letter).—Figs. 15 and 16 of the paper, giving basic data for typical storms on the three areas investigated, provide opportunity for various instructive studies. Computed run-off is obtained by applying the run-off factor to the 100% run-off rates as obtained by the unit-graph distribution of the rainfall. The writer used "net rainfall" and the author's unit graphs to study the same storms. "Net rainfall" (which, in amount, is equal to the run-off) is defined as precipitation minus losses, of which infiltration is much the largest and will be termed in this discussion "infiltration loss."

In accordance with the line of reasoning advanced by R. E. Horton, M. Am. Soc. C. E.,[7] a constant infiltration rate was determined for each storm. The constant infiltration rates for the three storms are, Area *A*, rain of September 8, 1926, 0.61 in. per hr; Area *B*, rain of August 27, 1921, 1.28 in. per hr; and Area *C*, rain of September 8, 1920, 0.45 in. per hr. Subtracting these rates of infiltration from the given precipitation rates minute by minute gave net rainfall rates, which were then distributed by the unit graph for the particular area to obtain computed run-off rates.

The computed run-off rates were then compared with the observed rates and the differences or errors obtained for each minute, from which, in turn, were computed the probable errors. For the storm of September 8, 1926, on Area *A*, the probable error for any one minute was 0.14 cu ft per sec, as compared with an approximate probable error, reported in the paper, of 0.21 cu ft per sec. This value and others given for the authors' method are only approximate, as the differences between computed and observed rates of run-off were scaled from Fig. 15. The probable error for the rain of August 27, 1921, on Area *B*, was found to be 0.19 cu ft per sec for any one minute, as against 0.08 cu ft per sec for the results given in the paper. For Area *C*, and the rain of September 8, 1920, the corresponding probable errors were 0.21 and 0.18 cu ft per sec, respectively.

This comparison indicates a close check of the degree of accuracy reported in the paper, although the run-off factor gives better results in two cases out of three. Possibly, improvements would be obtained by using a variable rate of infiltration loss and a variable run-off factor.

According to Mr. Horton,[7] the infiltration capacity of a natural soil is high when the rain begins, decreases rapidly at first, and approaches stability within an interval ranging commonly from 1 hr to 3 hr. If this is true a constant infiltration rate might not have been reached in the three storms studied, as they lasted less than 1 hr each. The writer's studies bear out the theory of a variable infiltration rate, although they do not show clearly the high rates of loss at the beginning of the rain with a graduated decline thereafter.

[7] "The Rôle of Infiltration in the Hydrologic Cycle," by R. E. Horton, M. Am. Soc. C. E., *Transactions*, Am. Geophysical Union, National Research Council of the National Academy of Science, June, 1933, p. 446.

A study of the algebraic sign and variation of the differences between computed and observed rates of run-off, and trials using a variable rate of infiltration, gave the following results for the three storms: The infiltration rate varied directly as the intensity of precipitation, but no attempt was made to determine the exact order of its variation. The approximate average rate of infiltration for 5-min periods for Area *A* ranged from about 1.0 in. per hr at the beginning of the storm (10:13 A.M.) to 0.6 in. per hr at 10:40 A.M., and decreased to about 0.5 in. per hr at 11:00 A.M. In Area *B* the beginning rates (average for 5-min intervals) were about 0.7 in. per hr, and these increased to 1.8 in. per hr at the end of the storm, when high intensity of rainfall occurred. In Area *C* an average infiltration rate of approximately 0.4 in. per hr continued for practically the entire storm, except for the two periods of high rainfall intensity, when it approached 0.5 to 0.8 in. per hr.

In all four peaks of the three storms the use of the average infiltration rates gave higher peak run-off rates than the observed rates, whereas the use of the run-off factor gave computed results lower than the observed rates for the higher peaks and higher than the observed rates for the two lesser peaks. The use of a rate of infiltration varying with precipitation, therefore, would bring the computed run-off rates nearer the observed rates in all four peaks, whereas a varying run-off factor would improve two of the computed results and add to the error of the other two. Accordingly, it appears that the use of a variable infiltration rate based on variations in precipitation intensity would give more consistent results than the use of a variable run-off factor.

Moreover, for all four peaks the computed run-off rates by the average infiltration method were larger than those obtained by the run-off factor—a difference which is inherent in the two methods. This is the result of subtracting a constant amount from the minute-by-minute rainfall, thus increasing the percentage of run-off from the higher rates.

Having an abridged copy of the original manuscript available, the writer compared average infiltration rates for the same storm (that of September 8, 1920) on the three areas. The results are given in Table 12. Column (5) shows the loss in inches per hour on an area that is 100% pervious, under the assumption of a straight-line relation between area of pervious ground and the quantity of infiltration. Comparison of Columns (3) and (5), Table 12, shows an apparent variation of average infiltration rate with intensity of rainfall.

TABLE 12.—RAIN OF SEPTEMBER 8, 1920

C	28	2.43	0.45	1.61

The authors have presented a comprehensive analysis of a valuable record of hydrologic data. The data and results are invaluable to the designer of sewers, and the basic data of the several storms provide an opportunity for the development and testing of methods of analysis of rainfall and run-off relations.

Merrill M. Bernard,[8] M. Am. Soc. C. E. (by letter).—Injecting modern thought into the science of storm-sewer design, the authors have given an interesting chronicle of an unusual experience in hydrologic research. It is particularly interesting to note the general applicability of the unit-hydrograph method to conditions ranging from those prevailing on small urban inlet areas of only 2 or 3 acres, with changes in rate of recorded rainfall at 1-min intervals, to those prevailing in stream basins covering several thousand square miles, utilizing U. S. Weather Bureau data in which rainfall is recorded at 24-hr intervals.

An absence of unit-time (1-min) records of rainfall in the studies recorded in this paper made it necessary for the authors to arrive at the factors fixing the shape and extent of their unit graphs "from a study of the records of a few short rains of fairly uniform intensities." That their method and the resulting equations are successful is demonstrated throughout the work and is one of the highlights of the paper. The resulting unit graph, however, is the same as that presented by LeRoy K. Sherman,[9] M. Am. Soc. C. E., being the hydrograph of 0.0167 in. of run-off depth (comparable to 1 in. of run-off depth from a 24-hr rainfall), applied throughout 1 min of rainfall at the rate of 1 in. per hr.

The writer has suggested the "distribution graph,[10] which shows the proportion of the run-off from any unit-time rainfall throughout the period of run-off, expressed as percentage of the total run-off. The conversion of the unit graph to the distribution graph, when rainfall is expressed in rate or in depth per unit of area, is accomplished by moving the decimal point two places to the right.

Table 13 constitutes a demonstration of the general application of the unit-hydrograph theory (on which Part I of the paper is based), applying methods developed on large basins to the rainfall of September 8, 1920, on Area *C*, shown in Fig. 15. In this case rainfall, expressed as rate in inches per hour, is reduced to inches of depth per minute and is recorded in Column (2), which makes it comparable to daily rainfall.

The unit graph for the area has been computed from Equations (1), (2), and (4) of the paper and the values for depth have been converted into the percentages of the distribution graph (see Column (3), Table 13). Rainfall (or, with the assumption of no loss, the theoretical 100% run-off) is distributed throughout the period of run-off by applying the 1-min figures of the distribution graph to rainfall depth, as shown in Columns (4) to (18), Table 13. Distributed rainfall (or 100% run-off) is now accumulated hori-

* Peak values.

zontally, giving the results for the author's theoretical 100% run-off graph, or the writer's pluviagraph (Columns (19) and (20), Table 13). The writer has distributed the figures computed for the unit graph beyond 14 min, throughout the distribution graph, accounting for the slight differences between the values in Column (22), Table 13, and those in Fig. 15.

As the storm of September 8, 1920 (Fig. 15), reached a peak in its later stages, it will be used to demonstrate the effect of the distribution of rainfall intensities throughout the period of rainfall on the 100% run-off or pluviagraph results. If the rainfall rates are arranged in order of magnitude, thereby assuming that the storm reached a peak in the first minute of rainfall, and that it was distributed as previously demonstrated (see Column (21), Table 13), the pluviagraph peak will shift from 5.33 ppm to 5.17 ppm without any appreciable change in value. It can be shown, however, that the most critical arrangement of intensities is that in which the high intensities are grouped around the minute that marks the peak of the distribution graph, which is, for the example given, the 6th minute of rainfall. Thus, on arranging rainfall and distributing it as previously explained (Column (22), Table 13), the pluviagraph peak shifts to 5.21 ppm and gives a result 12% greater than that developed by the storm itself.

The rate ratio, $P = \frac{\Sigma Q_t}{\Sigma Q_e}$, mentioned in connection with Fig. 17 of the paper, has been termed the "retention coefficient", by the writer in his recent paper,[11] but which should more properly be called the "storm, or flood, coefficient."

Under the heading "Suggestions for Application to Sewer Design," the authors place conservative limits upon the immediate use of their work in actual design, holding forth the hope that future research will make it possible to give proper values to such factors as j, k, and t_1 for conditions as they are combined in the typical city block. As sewer design is usually based on an estimate of the effect of future growth on surface conditions, these factors, no doubt, can be classified and standardized, as the now widely used "coefficient of imperviousness" and the coefficient, C, of the rational method.

The unit-hydrograph method has other advantages than those demonstrated by this paper. Assume, for example, that the means are at hand to produce acceptable values for the factors, j, k, and t_1, on an urban drainage area consisting of four inlet areas of 10 acres each. All are assumed to be alike in character, and, therefore, all have the same unit and distribution graphs. Other conditions are, as follows: The frequency to be met by design is, once in 10 yr; inlets are spaced at 1 000-ft intervals along a proposed sewer of circular section, beginning with Inlet No. 1; the slope ratio of the sewer gradient is 0.002; Kutter's n is 0.013; and, the 10-yr rainfall intensity equation for the locality is,

$$i = \frac{182}{t + 23} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

---

[11] "An Approach to Determinate Stream Flow", *Transactions*, Am. Soc. C. E. Vol. 100 (1935), p. 358.

A synthetic storm is developed by computing average rainfall rates for the various duration periods from Equation (6). These rates have been reduced to an average rate throughout any minute, and are the minute differences in the product of i and t-values, representing typical deviations from the averages defined by the intensity equation. Sound design demands the assumption of limiting conditions, and, therefore, rainfall is arranged in critical order (see Column (2), Table 14). It is recognized that this special arrangement of rainfall intensities tends to modify the conception of the storm as having a 10-yr frequency.

Retardation, through surface pondage, is reflected and accounted for in the distribution graph of the area, leaving the principal direct loss, particularly for rainfalls of short duration, to be that of infiltration, which is well expressed as a deduction, as suggested by Robert E. Horton, M. Am. Soc. C. E.[13] The problem here considered assumes an average infiltration loss of 0.50 in. per hr (Column (3), Table 14). The average rainfall excess, or that portion which appears as run-off, is given in Column (4).

The distribution graph for any one of the inlet areas is given in Column (5), Table 14. As developed on large basins, this graph represents the flow created by surface run-off from any rainfall, confined to a unit-time interval, proportioned throughout the period of run-off, and expressed as percentage of the total flow. The peak of such a flood is not created by the coincidental arrival of waters from all parts of the basin, but by the arrival of a flood wave, which has received its impetus and is developed and built up by direct run-off and lateral stream flow contributing throughout the combined length of the principal channels. Consistent similarity in shape and dimension of distribution graphs for a particular basin would indicate that the phenomenon occurs in practically the same manner for all unit-time storm periods. This suggests that a grouping of certain area units may be assumed, which, because of their position relative to the collection system, can be conceived as being enveloped by a time contour representing a period at the end of which the group has contributed its collective effect to the creation and acceleration of the flood wave. Under this assumption the distribution graph can be applied to the area of the basin, giving its "area distribution graph," in acres (Column (6), Table 14). The conversion of the distribution graph (percentage of volume of flow) to the area distribution graph (percentage of area) in no way affects the computed results; that is, the computed results are the same as if there had been no resort to this assumption.

The application of the area distribution graph to rainfall excess (in inches per hour or in cubic feet per second per acre) distributes each minute of such rainfall excess throughout the period of run-off, in cubic feet per second. The horizontal accumulation of these 1-min increments of run-off produces the total run-off from the area at any minute, measured at the inlet (Column (24), Table 14).

As the rainfall is considered to be uniform over the entire area of 40 acres, and as each inlet area is contributing to the flow of the sewer, the flow, as it

combines, will determine capacity. This synchronization is accomplished by determining the time taken by the run-off waters, as they combine, in passing through the various stretches of the sewer. A particularly satisfactory expression for average velocity in terms of the factors determinable in such a problem is that presented by R. L. Gregory and C. E. Arnold,[13] Associate Members, Am. Soc. C. E.

The sewer system in the problem begins with Inlet No. 1, Inlets Nos. 2, 3, and 4 contributing at 1 000-ft intervals progressing down the sewer. The purpose of Table 15 is to show how the flow from Inlets Nos. 1 and 2 may be combined with that of Inlet No. 3, the flow from Inlets Nos. 1 and 2 (Columns (2) and (3)) having been combined in the same manner. Column (4) gives the combined flow from Inlets Nos. 1 and 2 as such flow enters the stretch between Inlet No. 2 and Inlet No. 3. The average velocity, in cubic feet per second, computed by Equation (2), is shown in Column (5) and is converted to velocity, in feet per minute, in Column (6), from which the time in transit through the stretch is determined and listed in Column (7). Column (8) gives the period from the beginning of the rainfall to that minute at which the increment of flow enters the stretch, which, added to the time in transit through the stretch (Column (7)), determines the time of arrival at Inlet No. 3.

---

[13] "Run-Off—Rational Run-Off Formulas," *Transactions*, Am. Soc. C. E., Vol. 96 (1932), Equation (50), p. 1094.

In the meantime Inlet No. 3 has been discharging into the sewer. For instance, at the end of 20 min this inlet will have passed its peak discharge of 49.35 cu ft per sec and will be discharging at the rate of 31.66 cu ft per sec, while Inlet No. 2 will be delivering 40.48 cu ft per sec and Inlet No. 1, 49.35 cu ft per sec to the same point in the sewer.

If, then, the hydrograph of flow from Inlet No. 3 is adjusted to this position relative to Inlets Nos. 2 and 1 (Column (10), Table 15), the total flow, minute by minute, through the stretch between Inlets Nos. 3 and 4 becomes available. Columns (11) to (15), Table 15, show the arrangement of computations for the synchronized flow from the four inlets entering the stretch below Inlet No. 4.

No attempt has been made to take into account the changes in flow volume within 1-min intervals throughout the period of flow adjustment, involving the first and last 5 or 6 min. The synchronization, therefore, is less accurate for the extremes of flow, but is in agreement to the minute for the period between the 12th and 30th minutes (not all included in the published table).

To continue on the premise that fixed time intervals divide the drainage area into zones of like contributing characteristics, the area distribution graphs of the four inlets can be combined as the foregoing analysis has shown their flows to combine. The complete computation, of which Table 14 is an example, showed that the flow from Inlet No. 4 enters the stretch in the first minute; that from Inlet No. 3 reaches the stretch 3 min later; that from Inlet No. 2 at the end of 7 min, or 3 min later than that of Inlet No. 3; and the flow from Inlet No. 1 is 4 min later than that of Inlet No. 2.

Table 16 gives the sub-area combinations for each minute throughout the duration of run-off, producing an area distribution graph for the entire 40 acres (see Column (6)), applicable to the point of design below Inlet No. 4. This area distribution graph is now applied to the rainfall excess produced by the 10-yr storm of the problem in the same manner as that suggested in determining the run-off at the various inlets. The distribution and accumulation are made in the same manner as for the inlet. The result is the total run-off from the area, minute by minute, as it reaches the point of design, and is found to be the same as those of Column (15), Table 15, any slight differences being due to the adjustment in position between the four area distribution graphs to the nearest minute.

The advantages of having at any point under design an area distribution graph are obvious. With it various rainfall frequencies, rainfall intensities, infiltration rates, and run-off coefficients can be compared in terms of sewer dimension and cost. Another advantage of the hydrograph of flow, made available by the unit hydrograph, over a maximum only, as determined by other methods, lies in the ability to evaluate the effect of converting the several maxima of the hydrograph from sewer capacity to temporary backwater areas at the inlets. Particularly where the conditions produce distribution graphs, area distribution graphs, and hydrographs of flow of relatively short base and high peak, may this advantage become a factor in economical design.

It is possible, through the unit hydrograph, to analyze and correct what may be misconceptions in the "rational" method, a method which has enjoyed a wide use in the field of storm-sewer design and to the development of which the authors have contributed extensively. The method has back of it a ground of rationality that is entirely lacking in many of the older empirical formulas. Briefly, its theory is that a particular average rainfall intensity (of a given frequency) becomes the critical one for a drainage area when it is sustained throughout a period equal to the time of concentration for the area. The time of concentration is usually defined as that time necessary for the run-off from the "remote" portion of the area to reach the point of concentration. A further explanation of the theory is that even though higher rates will be reached for shorter "concentration" periods, run-off from them will be less than that from the critical intensity, because of the dissipating effect of surface pondage, together with the assumption that the rain will have stopped or so decreased in intensity before the end of each concentration period that the areas immediately adjacent to the outlet will have had time to relieve themselves of their run-off waters before the "remote" waters reach that point. Likewise, rainfalls of longer duration than the concentration period will be less effective, having lower average rates.

If the average rainfall intensities given by Equation (2), which are applicable to St. Louis, Mo., are distributed with the distribution graph reduced from the authors' unit graph for Area *C*, and each duration period is considered an independent rainfall, or synthetic storm, it will be found that, regardless of the coefficient or deductive factor used to reduce the theoretical 100% run-off to the actual run-off, average rates of rainfall for shorter periods than the period established by the base of the distribution graph, will produce potential run-off greater than that produced by the critical intensity.

The hypothetical problem used in the foregoing demonstration of the unit hydrograph method will here be solved by the rational method. The "inlet time" will first be taken as equal to the base of the distribution graph for the upper inlet, which is 16 min. By acceptable methods, the time in transit through the proposed sewer is found to be 11 min, giving a time of concentration of 27 min. From the rainfall-intensity formula, Equation (2), the corresponding critical intensity of 3.64 in. per hr is computed. The coefficient, C, is $\frac{3.14}{3.64} = 0.86$, and the rational equation becomes, $Q = C\ i\ A = 0.86 \times 3.64 \times 40 = 125.70$ cu ft per sec, producing a maximum flow which is 23% less than that developed by the unit hydrograph (Column (15), Table 15). Under the prevailing conception of concentration time, then, the rational method may give results that are too low, but the practical significance of this is lost in the wide range of values which have been given to the coefficient, C.

The foregoing conclusion, however, is predicated on the definition of concentration time as being equal to the base of the unit hydrograph of Inlet No. 1 plus time in transit, thus assuming that the "remote" area of the upper inlet is the last to contribute run-off to the point of concentration. The writer has found that, apparently, the unit hydrograph and rational methods may be brought into accord by defining concentration time as being equal to t_1, the time interval between the center of mass of rainfall and the flood peak or the "lag" interval, or the time position of the maximum ordinate of the unit hydrograph, plus any time in transit involved in reaching the point of concentration, and by converting average rainfall rates into average rate throughout any minute, arranged in critical order.

Following are the results of applying the rational method, so modified, to the Inlet No. 1 area, as shown in Table 14: Concentration time $t_1 = 6$ min (Column (5)); average of first 6 min of rainfall = 5.42 in. per hr (Column (2)); coefficient, $\frac{4.92}{5.42} = 0.91$; and (see Column (24) Table 14); $Q = C\,i\,A = 0.91 \times 5.42 \times 10 = 49.25$ cu. ft per sec.

The concentration time for the point of design below Inlet No. 4 is determined by adding to the "inlet time," or concentration time for Inlet No. 1, the time in transit through the sewer. The maximum discharge, as determined by the rational method, is as follows: The inlet time = 6 min; time in transit = 11 min(see Table 15); concentration time = 17 min; average rainfall intensity for 17 min = 4.55 in. per hr; coefficient, $\frac{40.3}{4.55} = 0.89$; and, $Q = 0.89 \times 4.55 \times 40 = 162.20$ cu ft per sec (see Column (15) Table 15).

As it has been customary to estimate inlet time at 5 to 20 min, results from the rational method have probably not been greatly affected by the apparent inconsistency revealed in the foregoing comparison; rather has the analysis upheld the rational method as a quick and reliable means of estimating maximum flow in storm sewers.

LeRoy K. Sherman,[14] M. Am. Soc. C. E. (by letter).—An important analysis of the rainfall-run-off relation on urban areas is presented in this paper, which is a step beyond the usual procedure based on the assumption of a uniform rate of rainfall during the storm period. Recently, the writer examined the rainfall and stream-flow records, due to forty storms, on a combined sewer area of 4 000 acres, in the Rock Creek Basin of the District of Columbia. The records were from self-recording gauges. In all these storm hydrographs the effect of varying intensity of rainfall produced a pronounced peak, in spite of the fact that storm durations generally exceeded the concentration period. This indicates that the assumption of a uniform rate of rainfall is not in accord with Nature's procedure and that, for certain areas, it may not be satisfactory. By an application of the unit hydrograph, the authors give a procedure which utilizes the actual varying intensity of the rainfall.

---

[14] Cons. Engr., Chicago, Ill.

In forecasting run-off from rainfall data by the unit hydrograph (or by any other method or formula), the chief problem is to determine the factor expressing loss in run-off due to infiltration or soil capacity. With few exceptions, Fig. 15 indicates a close agreement between observed and computed rates of run-off. The authors used the factor of average percentage of run-off applied to the 100% run-off graph.

Fig. 16 suggested the application of the storage equation to develop or apply the factor of infiltration loss. The storage equation is:

$$\text{Inflow Volume} = \text{Outflow Volume} \pm \text{Storage}\ldots\ldots\ldots\ldots(7)$$

which may be expressed:

$$\text{Rainfall} = \text{Run-Off} + \text{Infiltration} \pm \text{Storage}\ldots\ldots\ldots\ldots(8)$$

There are two unknown quantities in Equation (8). However, channel-storage depth is related to run-off rates and, likewise, storage depth on a plane surface is related to run-off rates. For the latter case the storage depth, d, is the same as the hydraulic radius, R. Therefore, the discharge rate is, $Q = C\sqrt{S\,d} \times d$, and,

$$\frac{Q}{Q_1} = \frac{d^{\frac{3}{2}}}{d^{\frac{3}{2}}_1}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(9)$$

in which Q_1 = the 100% run-off rate; d_1 = the storage depth corresponding to Q; Q = any given run-off rate; and d = storage depth corresponding to Q.

With the flow, Q_1, there is no infiltration loss. Therefore, Equation (7) can be applied to the data in Fig. 16 and d_1 may be determined for any rate of Q_1. The ordinate between the lines for accumulated rain and accumulated 100% run-off gives the depth of storage, d_1, at any time from the beginning of the storm. Values of d can now be computed by Equation (9). The values of d can be plotted for any given time in Fig. 16. These values will be on a line above, and somewhat parallel to, the line of accumulated 100% run-off. The ordinates between this line for d and the line for accumulated actual run-off give, by Equation (8), the accumulated loss to any given time.

The writer has applied the foregoing procedure for determining rate of loss per hour, or infiltration capacity, to the examples in Fig. 15. He obtained results as good, but no better, than the authors except in the case of the peak on Area A (Fig. 15). The writer also applied this storage equation procedure to a hypothetical case wherein he assumed the rates of rainfall and loss, in inches, as shown in Table 17. For comparison, the computed losses are also shown. Evidently, the procedure indicated by Table 17 did not offer any improvement over the use of the authors' application of average percentage of run-off.

Recently, the writer received a paper[15] by Robert E. Horton, M. Am. Soc. C. E., who makes successful use of the storage equation in the rainfall-run-off relation by taking cognizance of factors which the writer has neglected in this discussion.

To the present time the writer has secured the best results with the unit hydrograph method by applying the percentage of run-off directly to rainfall without the use of the intervening 100%-run-off graph or Bernard's pluviograph.[11]

TABLE 17.—HYPOTHETICAL CASE; COMPARISON OF TRUE VERSUS COMPUTED LOSSES

Day	Rain, depth	Loss, depth	Computed loss, depth
1	1.4	0.4	0.29
2	2.4	0.4	0.45
3	3.4	0.4	0.45
4	1.4	0.4	0.50
	......	1.60	1.69

This paper represents considerable careful work. The authors have presented valuable data and study applicable to problems in storm-sewer design and to the science of hydrology. Parts of the complete paper, as filed in Engineering Societies Library, New York, N. Y., are fully as important as the subject-matter submitted in the printed part. The writer refers particularly to the author's experiments on rates of infiltration during continuous rains.

W. W. HORNER,[16] M. AM. SOC. C. E., AND F. L. FLYNT,[17] ASSOC. M. AM. SOC. C. E. (by letter).—The discussions by Messrs. Snyder and Sherman develop the possibilities of an alternate study of the rainfall-run-off relation in terms of losses. In Part I of the paper, the writers made a fairly exhaustive effort to determine the relationship as a ratio. They found the ratios, or percentage values, to vary over a wide range and, for a large part of the data, were unable to allocate, satisfactorily, the variation to other hydrologic factors. As was shown in Fig. 18, all these ratios, whether taken between various summation values, or between values for particular periods (as for 5 or 10 min), or between peak rates, resulted in percentile curves of about the same slope. Each of the discussers has emphasized the point that the percentage factor must necessarily be a varying one. This is a condition which is well recognized by hydrologists, of course. Sewer designers have adhered to the use of a run-off-rainfall factor and the formula of the rational method, however, because of its simplicity of application, and for the reason that the dearth of real basic information on run-off from urban areas appeared to make further refinement in method unjustifiable.

---

[15] "Surface Runoff Phenomena," by Robert E. Horton, *Publication 101*, Horton Hydrological Laboratory, February 1, 1935, Edmonds Bros., Inc., Ann Arbor, Mich., Publisher.

[16] Cons. Engr., St. Louis, Mo.

[17] Civ. Engr., formerly with Sewer Design Dept., City of St. Louis, St. Louis, Mo.

The writers are impressed by the sample demonstration offered by Mr. Snyder, as well as by the reasonableness of Mr. Sherman's presentation. It is entirely possible that an alternate analysis of all the information used by the writers, involving the infiltration losses as determined by Mr. Snyder, and the further evaluation of storage as discussed by Mr. Sherman, might result in a set of relatively consistent values having a definite relationship to such basic characteristics as slope, shape of area, and character of surface coverage. Some of the relationships would probably be of the same general order as those suggested by Mr. Bernard in another paper.[18]

The writers agree with Mr. Snyder that a constant infiltration rate could not be used satisfactorily for rains of less than 1 hr in duration. A desirable approach to such a study, accordingly, would be along the lines of determining infiltration capacities for each of the particular areas (which capacities might be expected to vary on a seasonal basis), and also the probable rate of reduction of infiltration within the first hour or two of the storm. It would be necessary, however, to determine the proportionate part of the precipitation going into (temporary) surface storage during the rise of the hydrograph. This also is determinable, possibly, from the same data.

The recent studies by Robert E. Horton, M. Am. Soc. C. E., referred to by Mr. Sherman,[15] using in part the data presented in this paper (privately published and, unfortunately, not available to this discussion) seem also to indicate that satisfactory basic data of this type could be derived from the information originally analyzed by the writers. If such an analysis was found to produce reasonable values of infiltration and storage, some development of Mr. Sherman's Equation (8) might be substituted for the rational formula of sewer design.

Illustrative of how an analysis of basic rainfall and run-off data, such as are supplied by the St. Louis records, might throw some light upon the variation of infiltration rate and temporary storage or detention, the data for three storms at Area *A* are presented in Figs. 31, 32, and 33, together with a detailed analysis of the various curves derived from the basic data by various methods. Fig. 31 gives the data for the storm of July 23, 1931, which was chosen for its short duration and unusually uniform rate of precipitation. Fig. 31 (*b*) follows the method suggested by Mr. Horton and referred to by Messrs Snyder and Sherman. The basic data as to rainfall and run-off are represented by the $\Sigma\, i$-curve and the $\Sigma\, Q$-curve, respectively. For simplicity, infiltration is assumed to be at a constant rate and the mass infiltration curve is a straight line through the origin at the beginning of rainfall and with a final ordinate at the end of run-off equal to the difference between total rainfall and total run-off. (The value of "infiltration" thus determined, is in error in that it includes permanent retention and other losses.) The mass net rainfall curve is obtained by subtracting the ordinates to the mass infiltration curve from corresponding ordinates of the mass rainfall, or $\Sigma\, i$-curve. The intercept on a given time ordinate between the net rainfall curve and the mass run-off curve represents the depth of surface detention, including both sheet and channel storage, which, as pointed out by Mr. Sherman, bears a direct relation to the rate of run-off.

---

[18] "An Approach to Determinate Stream Flow", *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 358.

On further consideration, the writers find that this rather unsatisfactory approach may be avoided entirely, and the desired item of mass loss and of detention may be determined directly from mass curves based on the unit graph, as originally presented in Fig. 15 of the paper.

Fig. 31 (*c*) illustrates the method of obtaining the depth of surface detention by the application of the unit graph formulas to the same basic data. In this case, the mass 100% run-off, or ΣQ_c-curve, is obtained by applying the unit graph formulas to the rainfall data. The surface detention is then determined by the intercept on the time ordinates between the Σi-curve and the ΣQ_c-curve.

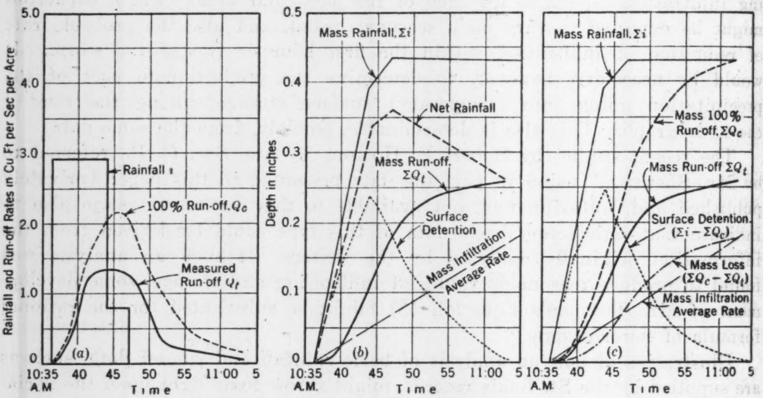

FIG. 31.—STORM OF JULY 23, 1931, AT AREA *A*.

The surface detention curves as determined by the two methods show a remarkable similarity in essential features despite the radical difference in the methods, which indicates that the unit graph formulas as developed by the writers may be close approximations to the true values. Such being the case, the procedure may be extended to determine the probable variation in the value of the rate of water loss (of which infiltration forms the greater part) during the progress of a storm. The accumulated water loss represented by the mass loss curve, Fig. 31 (*c*), is determined by the intercepts on the time ordinates between the ΣQ_c-curve and the ΣQ_t-curve.

At first glance, the comparatively low rate of water loss during the early minutes of the storm may seem surprising, but further study shows that this is quite reasonable when it is considered that the area in question is composed of both pervious and impervious surfaces and that the first water to reach the inlet (and, in fact, the only water to reach it for some time) is that which has fallen upon the adjacent paved streets, which are highly impervious surfaces. Naturally, then, the loss is low. As the pervious areas (in this case mostly sodded), begin to contribute water to the inlet, the percentage of loss becomes higher and the curve becomes steeper, and, for a considerable period (almost 10 min), the rate of loss is constant. This loss may well represent the average rate for the entire area, pervious and impervious. Soon after the cessation of rainfall, the rate begins to decline, which indicates that the run-off now consists mainly of gutter flow, in which case, again, the loss would naturally be low due to the impervious surface on which the water is flowing. It seems reasonable to infer that a straight line representing constant infiltration (such as in Fig. 31 (*b*)) would only apply to areas where the entire surface was of the same degree of permeability.

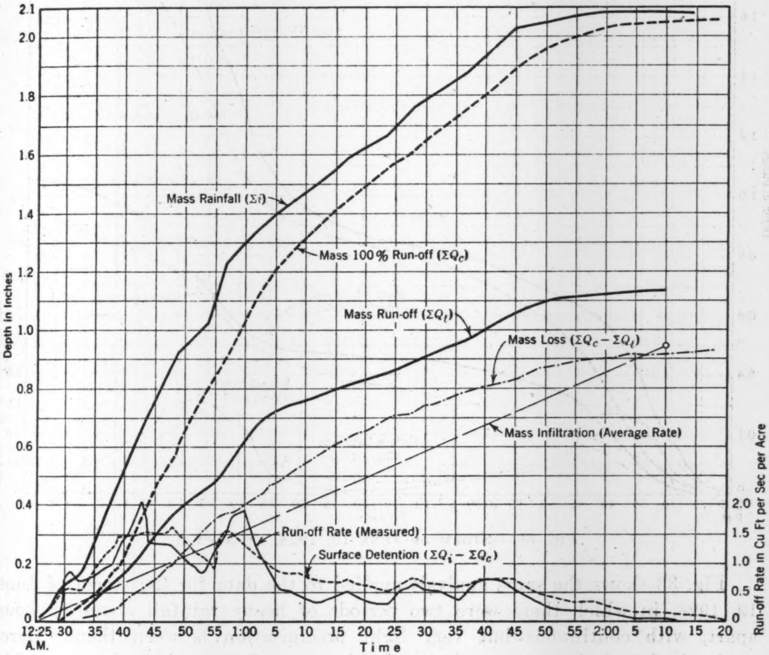

FIG. 32.—STORM OF SEPTEMBER 15, 1914, AT AREA *A*.

Fig. 32 gives the basic data and derived curves for the storm of September 15, 1914, which may be described as an "average rain" (Fig. 38, introduced subsequently, shows the rainfall pattern).

The loss curve in this case shows the same general characteristics as the one shown in Fig. 31 (*c*), the minor differences being explained by the different rainfall pattern. There is again the low initial loss and the high rate of loss during the period of high precipitation, when the pervious areas are contributing their full quota of water. After the period of heavy rainfall the gutter flow, which includes much of the water falling during the heavy

rainfall period, tends to reduce the average rate of loss, and, as the rate of rainfall becomes less and less toward the end of the storm, the rate of loss declines due to the predominance of gutter flow.

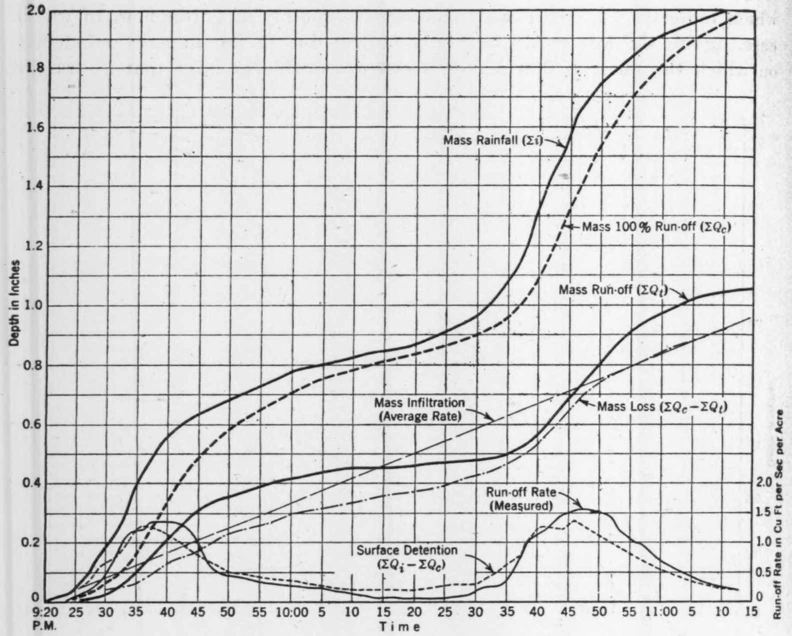

FIG. 33.—STORM OF JUNE 19, 1928, AT AREA *A*.

Fig. 33 shows the same analysis applied to the data for the storm of June 19, 1928, in which there were two periods of heavy rainfall about an hour apart, with continuous but very light precipitation between them. Here, again, is found the same variation in the rate of loss, which is susceptible to the same explanation given in the foregoing analysis. To the beginning of the second period of heavy rainfall, the variation follows the same general pattern as in Fig. 32. The sharp rise thereafter is due to the fact that the pervious areas are again contributing a large share of the water appearing as run-off, whereas during the lull between the storms the impervious areas were contributing most of the water due to the fact that the infiltration rate on the pervious area was nearly or quite as great as the rate of precipitation.

In the three storms (Figs. 31, 32, and 33), the close relation between the depth of surface detention and the rate of run-off is obvious. Fig. 34 shows an attempt to arrive at the mathematical correlation between these two factors by plotting the values for depth of surface detention for several peaks, in the aforementioned storms and two others, against corresponding

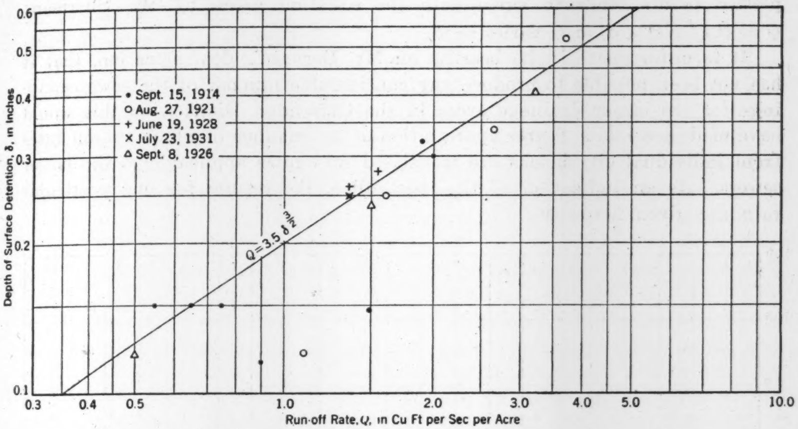

FIG. 34.—RELATION BETWEEN PEAK VALUES, SURFACE DETENTION, AND RUN-OFF RATE, AREA *A*.

run-off peaks in the same storms. The results are from a small number of storms, and both pervious and impervious areas are represented in varying proportions at different peaks. However, the general trend of the

plotted points tends to agree with the equation given by Mr. Sherman: $Q = C\sqrt{S\,d} \times d$, or Q varies as $d^{\frac{3}{2}}$.

It is unfortunate in its bearing on Mr. Bernard's demonstration, that it has not been possible to produce any considerable number of the sewer gaugings for the larger drainage areas in the Clarendon District, as this would have made possible a clearer appreciation of the manner in which run-off rates from individual city blocks are translated into rates applicable to the larger sewers. As an indication of the possibilites, the results for one particular rain are given herewith.

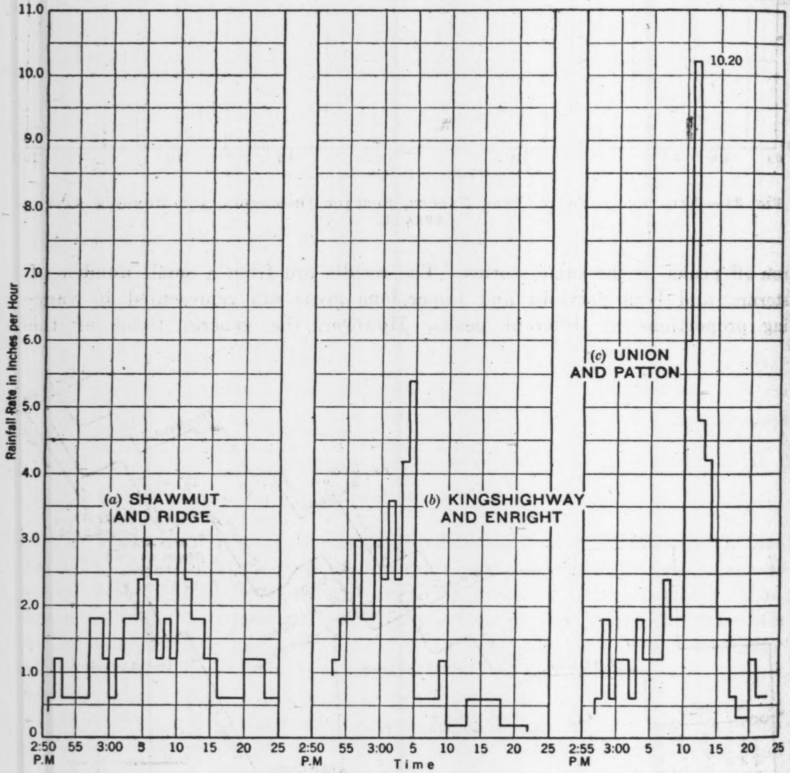

FIG. 36.

Fig. 35 is a plat of the Clarendon District, showing the location and sizes of the main sewers (the grades of which vary from one-third to two-thirds of 1%), the location of the principal pressure gauges in the main sewers by number, and the drainage area tributary to each. The location of the three tipping-bucket rain-gauges (marked *a*, *b*, and *c*) is also shown on this plat, as well as the location of the two city blocks from which the data for the original paper were collected.

Fig. 36 shows the rain record of July 10, 1920, at three rain-gauges, showing the wide variation in pattern possible even within a 600-acre district. This particular rain also showed a definite tendency to progress up the drainage area. Fig. 37 shows the interpolated rain diagram applicable to the centers of the drainage areas above each group of sewer gauges, and, on this same diagram, have been plotted the hydrographs of sewer flow for each gauge in the group. For comparison, the average rainfall rate for the approximate critical time of 20 min is shown in Fig. 37 (*a*) and Fig. 37 (*b*) and the average rate for 25 min is shown in Fig. 37 (*c*). Comparing these rain values with Fig. 23, it would appear that this rain would have a frequency of about 1½ yr.

The higher run-off rates, in cubic feet per second per acre, in Fig. 37 (*c*) may be explained in part by the longer and more compact rain diagram, and, in part, by the considerable width of the drainage basin in its lower sections. The lower rates, averaging 0.75 cu ft per sec per acre for the upper groups of gauges on Fig. 37(*a*) and Fig. 37 (*b*), give a good example of the effect of surface detention on run-off rates in short rains.

Comparing the rates at the three groups of gauges with the expected run-off rate from single city blocks, as given in Fig. 23 of the paper, it is seen that the run-off of 0.75 cu ft per sec per acre is less than one-half the expected rate for a 20-min storm of 1½-yr frequency for Area *A* and about 70% of the corresponding value for Area *B*. A rough comparison would seem to indicate that, for a composite area in which the Area *A* type of city block is predominant, the run-off rate in the sewer is 50% of the expected run-off of the single city block. For the lower gauges, shown on Fig. 37 (*c*), it would appear that the sewer-flow rate might be as much as 75% of that from an average city block. It is expected that a full analysis of this work will provide some excellent factors for use in calculations of the type developed by Mr. Bernard.

Throughout this entire study, it is apparent that the simplest method of expressing the relation between rainfall and run-off is by the volumetric ratio between the accumulated run-off and the accumulated rainfall. When this ratio is derived by comparing the accumulated run-off for a given time with the accumulated rainfall for a time earlier by the amount of the mean lag, for the location in question, it may be applied quite simply to approximate solutions of storm-flow problems. Figs. 38 and 39 show the results of this method as applied to the rain of September 15, 1914, at Area *A*.

The relation between the two factors seems to be remarkably constant in many of the storms that have been investigated, and there is reason to believe that, had the synchronism between the rainfall and run-off records been more reliable, this constant relation would have been more general. Fig. 38 shows how, by multiplying the rate of rainfall for each minute by the average ratio (0.54), as derived from Fig. 39, and plotting the result 4 min later, a graph is constructed which, in its peak values, and general configuration, closely approximates the measured run-off curve. This suggests a simple method for predicting the (approximate) probable run-off from a given rainfall when

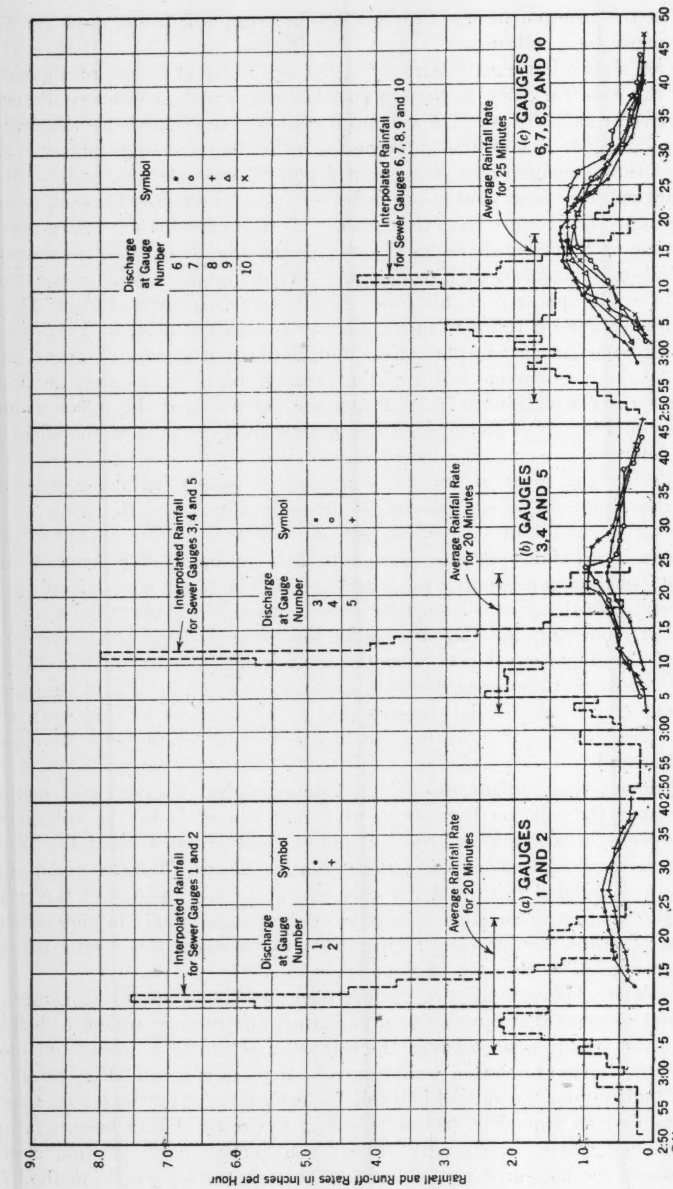

FIG. 37.—RAINFALL AND RUN-OFF DATA, STORM OF JULY 10, 1920.

the mean run-off factor and the lag are known for the location in question. Unfortunately, the run-off factor varies over wide limits from one storm to another, as shown in Fig. 18 of the paper.

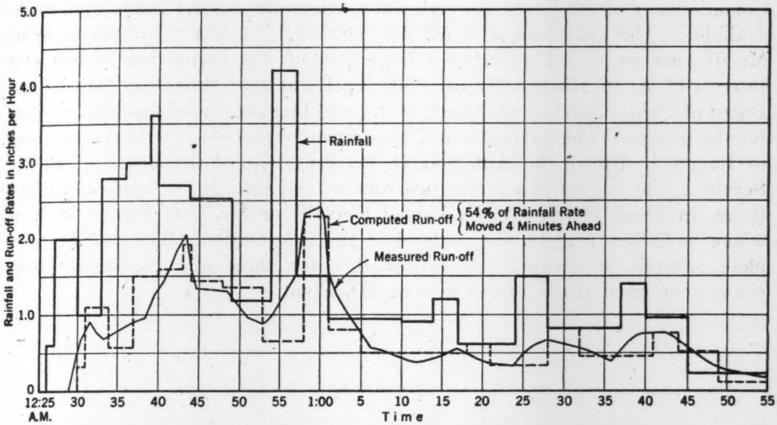

FIG. 38.—RAINFALL AND RUN-OFF, BELT AND RIDGE AVENUES, SEPTEMBER 15, 1914.

Little can be added to what Mr. Bernard has said about extending the unit graph method to large urban areas, except to commend the very constructive work he has done toward enlarging the scope of the data submitted in the paper and making it more useful to the sewer designer.

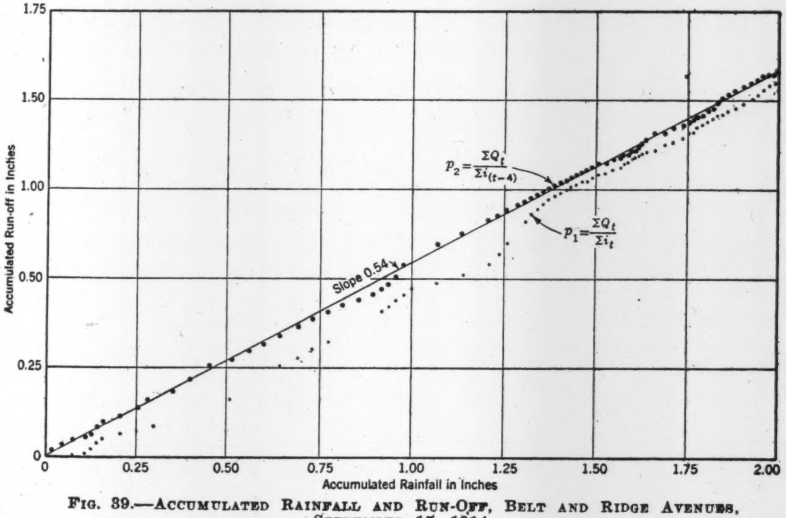

FIG. 39.—ACCUMULATED RAINFALL AND RUN-OFF, BELT AND RIDGE AVENUES, SEPTEMBER 15, 1914.

Acknowledgments.—The St. Louis Research Program, of which the data presented in the paper are a part, was developed by one of the writers, Mr. Horner, under the inspiration of the late James A. Hooke, formerly Sewer Commissioner of St. Louis, through whose energetic support funds were made available. The experimental work was continually under the supervision of Mr. Horner up to 1933; during a large part of this period the sympathetic interest of E. R. Kinsey, M. Am. Soc. C. E., at that time President of the Board of Public Service, was effective in providing continued financial support for the project. The publication of Departmental records is with the approval of Baxter L. Brown, M. Am. Soc. C. E., President of the Board of Public Service. The supervision of the instruments and records has been, at various times, in direct charge of Mr. Leland Chivvis, or Mr. Guy Brown, each of whom had some part in the analysis of the information. The present complete analysis of accumulated information for three city blocks has been the specific work of one of the writers, Mr. Flynt.

THE SILT PROBLEM

By J. C. Stevens,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Harry G. Nickle, E. W. Lane, Frank E. Bonner, Morrough P. O'Brien, Harry F. Blaney, W. W. Waggoner, Philip R. R. Bisschop, Herman Stabler, N. C. Grover, and J. C. Stevens.

Synopsis

All the basic data that the writer could secure on the silting of reservoirs, where actual capacity surveys have been made to determine the extent of silting, are contained in this paper. Remedial measures for silt elimination are presented and discussed. A table contains a brief of all data on the silt transported by the streams of the world. The physical laws of silt transportation are outlined, with pertinent discussion. The control of silt in canals, reservoirs, and on water-sheds is then considered. The paper closes with data and discussion on the origin of silt.

The original paper, containing additional data and more extended discussion, is on file in Engineering Societies Library, 29 West 39th Street, New York, N. Y.

Statement of the Problem

The word, "silt", as used in this paper, includes in its definition all material transported by flowing water whether carried in suspension or transported as bottom load. Silt originates from the disintegration of rocks by the climatic agencies of rain, wind, and frost, and by chemical agencies in water and air. The effect of such disintegration is evidenced by the wearing down of mountains, the gullying of their slopes, the filling of valleys, the extension of deltas into seas—in brief, the leveling of mountain ranges into plains.

Note.—Early in its existence the Special Committee on Irrigation Hydraulics selected the subject of "The Silt Problem" as one of ten for study and research. This paper was submitted to the Committee by its author, and the Committee has recommended its publication by the Society. Published in October, 1934, *Proceedings*.

[1] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

Geological history is marked by a succession of sedimentations and uplifts, in which varying climates, water supplies, vegetation, glaciation, and volcanism have played and are playing all-important parts. The processes of disintegration, erosion, transportation, sedimentation, mountain building, and plain leveling are still in progress and are as effectual as ever. Existing topography is a complex residual of these processes in which unnumbered eons have contributed to its present configuration.

Man can not hope to halt the processes of mountain erosion and plain building. The land he cultivates could not exist except for these forces. He must expect that rains will gully his fields, or cover them with mountain débris, and that the streams will continue to carry sediments that will fill the canals and reservoirs.

Man's problem lies in utilizing the agencies of sedimentation to his advantage where possible and in opposing the nullification of his endeavors by controlling them through whatever forces lie at his command.

Data on Silting of Reservoirs

The construction of large storage reservoirs on some of the silt-laden streams of the West has focused attention on the part sedimentation will play in the future history of Western civilization.

An empire exists below the storage reservoir that has been created by the Elephant Butte Dam, on the Rio Grande, in New Mexico. The land is phenomenally productive. This region embraces a substantial unit of civilization the very existence of which hangs upon the integrity of a storage reservoir to impound and deliver the water so vitally necessary to life.

The reservoir created by Elephant Butte Dam is slowly being deprived of its ability to store water. Silt is being deposited at an average rate of 20 000 acre-ft per yr. Its original capacity will be so depleted in two or three generations that the civilization now dependent upon it will have to seek other sources of water supply and storage.

Fortunately, sites are available where other reservoirs may be constructed; and, after these are gone, others will doubtless be found. Furthermore, the present dam could be raised to increase its storage capacity; but what of the ultimate future, when all available storage sites have been exhausted? Must those now fertile areas revert, ultimately, to the sage-brush and the cactus? Will sedimentation, that made possible this vibrant civilization, ultimately sound its death knell? How long can this episode in the annals of civilization continue and what can Man do to prolong its existence?

The Boulder Dam, in the Colorado River, will create the largest storage reservoir in the world. Upon it will depend not only the security of the entire Imperial Valley against damages from floods, and the irrigation of millions of acres of land, but also the domestic and irrigation supply for the metropolitan district of Southern California. The ability to furnish power to the people in seven States also hinges upon its functioning. Unless remedial measures are adopted, this reservoir will become virtually useless, by reason of silt deposits, before the passing of the fifth generation.

Fortunately, as on the Rio Grande, a number of other storage sites are available on the Colorado River. Ultimately, however, within some definite number of generations, the fact must be faced that all these reservoirs will have become useless for storage purposes. The dependent peoples must then be reduced to those that can subsist on the areas which the unconserved flow of the river will irrigate.

It is not the writer's intention to paint a dark picture, but rather to stimulate a more intensive study and an intelligent research that will ultimately effect a practical solution of this problem. The menace exists; it is real; and unless something constructive can be evolved, civilization in these regions must eventually decline. It is unfair to sit smugly complacent and to pass this problem flippantly on to future generations. The engineer should be equal to the task of finding a solution, but it will take many years of experimentation and study, and he should be at the task, amply financed.

The results of the sedimentation of reservoirs for which the extent of depositions have been determined by actual surveys, are given in Table 1. In order to make the data comparable, capacities and silt deposits have been referred to the controlled spillway level. On some reservoirs the silts deposited above this level may be a considerable part of the total, but this does not rob the reservoir of storage capacity. The following supplementary data pertaining to Table 1 are offered.

Boulder Reservoir (Under Construction).—Of the total capacity of this reservoir, 9 500 000 acre-ft. will be reserved for flood protection, 7 000 000 for silt, and 14 000 000 for irrigation. The maximum recorded discharge was 210 000 cu ft per sec on June 18 and 19, 1921. The maximum known flood occurred in 1884, for which the discharge was between 250 000 and 300 000 cu ft per sec (6*a*).[3] The spillway capacity is 400 000 cu ft per sec, exclusive of outlets for power and irrigation.

Elephant Butte Reservoir.—Capacity surveys for silt deposits in this reservoir were made in 1916, 1920, and 1925, with the results shown in Table 2(*a*). The maximum recorded mean daily discharge entering the reservoir area was 33 000 cu ft per sec on October 11, 1904. The overflow spillway capacity is 16 000 cu ft per sec. In addition, there are four regulating gates with a combined capacity of as much more.

Roosevelt Reservoir at Junction of Salt River and Tonto Creek.—This reservoir is 70 miles northeast of Phoenix, Ariz. Capacity surveys for silt content have been made as shown in Table 2(*b*). The maximum recorded inflow was 94 800 cu ft per sec on January 19, 1916. The spillway capacity is 150 000 cu ft per sec.

Keokuk Reservoir, at Keokuk, Iowa.—The Keokuk Reservoir was completed in 1913. It extends 42 miles up stream from the dam, and has a surface area of 25 200 acres and a capacity, at Elevation 518, of 370 300 acre-ft based on a survey made in 1891. The maximum recorded inflow

was 314 000 cu ft per sec in May, 1888. Since the dam was constructed, the maximum flood was 242 000 cu ft per sec on April 16, 1922.

Hales Bar Reservoir.—The dam is near Guild, Tenn., and was completed November 1, 1913. The normal pool level (crest of dam) is at Elevation 626.2. The original capacity of the reservoir to the crest of the dam was 142 000 acre-ft; 3 ft of flash-boards added later, increased this capacity to 156 000 acre-ft. Surveys were made of the Tennessee River in 1889–1891 by the United States Corps of Engineers. In 1905, the Power Company made a survey for flowage areas. In the fall of 1930, the U. S. Engineers made a capacity survey of the entire reservoir.

Parksville Reservoir (Also Called Ocoee No. 1).—The dam is 12 miles above the mouth of the Ocoee River, at Parksville, Tenn. About 70% of the drainage area is forest and wood lots. The Ducktown Mining District presents a striking example of the destruction of forest lands by the fumes from smelters, roast ovens, and incidental activities. About 20 sq miles have been completely denuded. Erosion is excessive as the poisonous gases will not permit the growth of any vegetable matter. This condition, and the clayey soils and excessive rainfall to which this basin is subject, offers a complete explanation of this most flagrant example of unnatural erosion.

Surveys to determine the silt content were made by The Tennessee Electric Power Company in 1917, 1921, and 1929, and by the U. S. Engineers in the fall of 1930. The early surveys included only the up-stream half of the reservoir, but that of 1930 covered the entire reservoir. The results of the capacity surveys (70*d*) are given in Table 2(*c*).

Lake McMillan North of Carlsbad, N. Mex.—The original dam was completed by the Pecos Irrigation District, in 1894, with a capacity of 32 500 acre-ft at the spillway (Elevation 3 258.9). The project was greatly damaged by floods in 1906 and thereupon was taken over by the United States Bureau of Reclamation. The spillway has been raised repeatedly, the last time in 1915 to Elevation 3 267.7, to which the capacity surveys in Table 2(*d*) have been referred. The great reduction in the rate of silting since 1915 has been due to a dense growth of tamarisk (salt cedar) on the flats at the upper end of the reservoir. This growth induces the river to drop most of its silt in the valley just above the reservoir. Fig. 1 shows

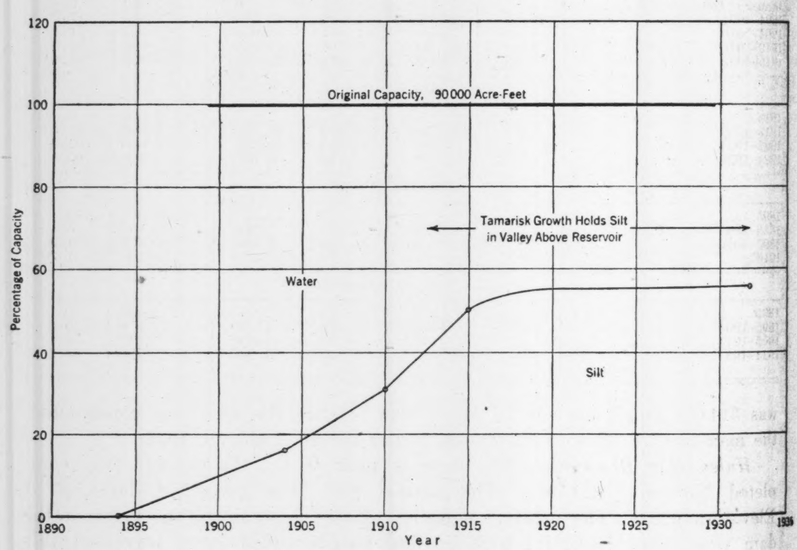

FIG. 1.—SILTING OF LAKE MCMILLAN.

the silting curve for this reservoir. Nearly one-third of the silt deposited during the last period resulted from the flood of April, 1915, during which the maximum recorded inflow of 42 000 cu ft per sec was observed. The nominal spillway capacity at the dam is 35 000 cu ft per sec.

Guernsey Reservoir.—This is a regulating reservoir on the North Platte River near Guernsey, Wyo. Storage began in March, 1927. Surveys for silt were made by soundings in February, 1929, showing 3 010 acre-ft of deposits; in January, 1931, 5 970 acre-ft; and in February, 1933, 8 400 acre-ft. Silt was found mostly in the old river channel in the up-stream half of the reservoir. The normal flow of 1 650 000 acre-ft is the average inflow for the period, 1909–1932. The maximum discharge was 21 000 cu ft per sec, on June 28, 1917.

Austin Reservoir, Austin, Tex.—The first dam was completed in May, 1893, and failed in April, 1900. It was rebuilt in 1911–1913. During the interval, 1900 to 1913, much of the silt deposited in the old reservoir was washed out. The new reservoir, with a spillway 9 ft lower than the old, had 65% of the capacity of the old reservoir when it was first filled in 1913. Capacity surveys were made in the late summer of the years indicated in Table 2(*e*). They refer to the new reservoir.

The spring flood of 1922 deposited more silt in two weeks than had accumulated in the previous five years. The maximum recorded discharge over the spillway was 151 000 cu ft per sec on April 7, 1900, just before the dam failed.

Lake Worth, Near Fort Worth, Tex.—The average water supply from October 16, 1923, to September 30, 1930, was 211 800 acre-ft per yr. This reservoir provides water for the City of Fort Worth. The maximum recorded discharge was 7 600 cu ft per sec, on November 18, 1923.

Cucharas Reservoir, Arkansas River Drainage East of Pueblo, Colo.—The drainage area is 6 000 to 12 000 ft high, composed of narrow valleys and eroded mesas sparsely timbered, except in the higher altitudes. No actual surveys of silt content have been made, but it is known to be silted to an average elevation of 68.0 ft (spillway level, 106.0 ft), for which the capacity is 7 850 acre-ft.

Cheoah Reservoir at Mouth of Cheoah River, Near Fairfax, Tenn.—The total drainage area of the Little Tennessee River is 2 650 sq miles, of which 60% is forest lands, most of which have been cut over. The Cheoah Dam and Hydro-Electric Plant were completed in 1919. The original capacity at normal pool level (Elevation 1 275.8) was 41 600 acre-ft. The Aluminum Company of America made a survey for silt content in the upper 2½ miles of the reservoir in 1922. The U. S. Engineers made a complete survey of the reservoir in the fall of 1930.

Sweetwater Reservoir.—This reservoir is in San Diego County, California. It was originally built in 1888, to a height of 70 ft above the outlet. The spillway was raised 5 ft in 1896. The height of the dam and spillway was again increased 15 ft in 1915. The present (1932) spillway is 90 ft above the outlet; capacity surveys were made in 1887, 1895, and 1917, and a partial survey in 1927, with the results shown in Table 2(*f*). Most of the silt was deposited in flood years. Stream-flow records cover 42 climatic years, from 1887 to 1929. The maximum inflow occurred in 1915–16 (160 000 acre-ft). The minimum was zero during the four years ending September 30, 1900, 1902, 1903, and 1904. During nine years (1895–1904), the total water supplied was only 9 290 acre-ft. The maximum recorded discharge was 45 500 cu ft per sec, on January 27, 1916.

Lake Chabot, Southwest of Oakland, Calif. — The drainage area is densely covered with brush and redwood. Capacity surveys referred to Spillway Gauge 83.5 are: For 1875, 17 000 acre-ft; for 1900, 15 500 acre-ft; for 1911, 13 800 acre-ft; and for 1923, 13 500 acre-ft.

White Rock Reservoir.—This reservoir is 4 miles east of Dallas, Tex. Of the drainage area, 75% is cultivated land. A survey in 1910 (not very accurate) gave a capacity of 21 500 acre-ft at Elevation 140.15 (local datum). The survey of 1923, which was made accurately, showed a capacity at Elevation 140.5 of 19 535 acre-ft, and 16 896 acre-ft, at Elevation 138.5 (spillway level).

Boysen Reseroir in Fremont County, Wyoming.—The dam was completed in 1911 to create head for a hydro-electric plant. Storage was of secondary consideration. Soundings were made through the ice on December 5, 1922, and again on January 23, 1924. On the latter date the reservoir was practically full of silt to the spillway level. The deposit of 13 000 acre-ft of silt is largely estimated. The power plant has carried no load since May, 1928, on account of silt accumulations.

Zuñi Reservoir.—The reservoir is at Blackrock, N. Mex., in the Zuñi Indian Reservation. The dam was completed in 1907. Capacity surveys have been made by sounding through the ice during each year when it was possible. When the ice did not cover the entire silt deposits, the reservoir

TABLE 3.—CAPACITY SURVEY OF ZUÑI RESERVOIR IN NEW MEXICO

Date of survey	Period, in years	Capacity, at Elevation 998.3, in acre-feet	Run-off for period, in acre-feet	SILT DEPOSITED DURING PERIOD		CAPACITY LOST

topography from the preceding survey was used for that part above the ice. The deposits between ice level and top of flash-board level (Elevation 998.3) for some of the years are, therefore, probably not included in the totals given in Table 3.

The survey of July, 1932, was a topographic survey of the entire reservoir taken on the surface of the silt deposits while the reservoir was practically empty. It is probably the most accurate survey that has been made.

Protective works to hold the silt on the water-shed were begun in 1923 on Rio de Los Nutrias, the principal silt-producing tributary. In July, 1931, a hole was blasted in the gate tower for the installation of a 4 by 6-ft sluice-gate, which was installed on October 15, 1931. Between these dates 500 acre-ft of silt were sluiced from the reservoir. Sluicing operations have continued each year whenever water was available. The gain in capacity for the surveys of 1928 and 1932 is partly due to sluicing and perhaps partly to inaccuracies in the preceding surveys. Fig. 2 shows the rate of silting. All capacities are referred to the top of the present flash-boards (Elevation 998.3, old datum, = 6 637.1, United States Geological Survey datum).

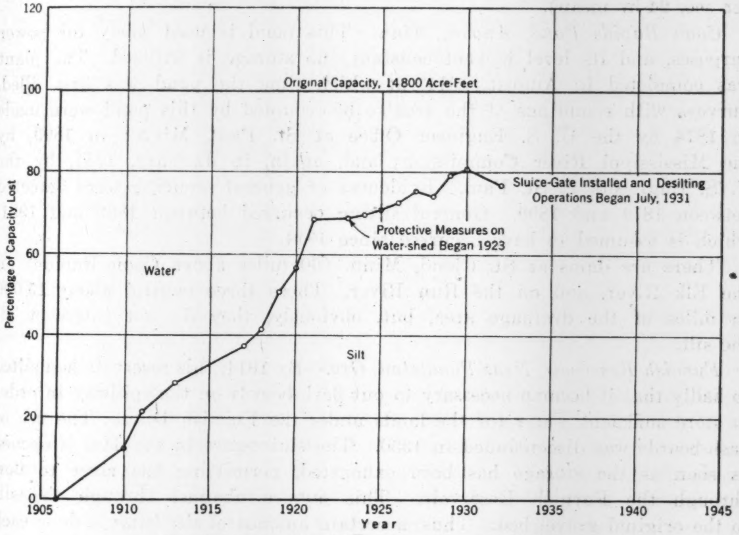

FIG. 2.—SILTING OF ZUÑI RESERVOIR, 1906–1930.

Gibraltar Reservoir.—Water for the City of Santa Barbara, Calif., is stored in this reservoir. The drainage area is sparsely covered with brush and small trees. Most of the silt came after the fire of 1923, which burned over the greater part of the water-shed. The water supply is very erratic. The year, 1921–22, yielded 65 500 acre-ft, whereas in 1923–24 the inflow was only 2 000 acre-ft. The maximum mean daily discharge (outflow) was 7 250 cu ft per sec, on April 8, 1926.

Lake Michie.—This reservoir stores water for the City of Durham, N. C. Ten permanently marked cross-sections of the reservoir were established just before filling it in the fall of 1926. Silting observations were made at these cross-sections in September, 1930, showing an average silt deposit of 8 to 10 in. Some of this deposit was due to wave action washing the top soil of the lake margin into the lake. The normal flow of 124 cu ft per sec is the average of the years, 1925–26 to 1929–30, inclusive.

Sterling Pool.—This is formed by the Government dam at Sterling, Ill. The dam and locks were constructed in connection with a feeder for the Illinois and Mississippi Canal. Soundings were made at a series of cross-sections above the dam in 1912–13.[8] The soundings in 1930 were made from the same base lines. During the 18-yr period a total of 3 360 000 cu yd of silts were deposited, while 123 000 cu yd of material were scoured. The maximum recorded flood was that of May 16, 1929 (29 200 cu ft per sec, 24-hr mean).

Coon Rapids Pond, Anoka, Minn.—This pond is used solely for power purposes, and its level is kept constant; no storage is utilized. The plant was completed in August, 1914, at which time the pond was first filled. Surveys with soundings of the area to be occupied by this pond were made in 1874 by the U. S. Engineer Office at St. Paul, Minn.; in 1899, by the Mississippi River Commission; and, again, in January, 1931, by the U. S. Engineers at St. Paul. Evidences of general scouring were detected between 1874 and 1899. General silting occurred between 1899 and 1931, which is assumed to have occurred since 1914.

There are dams at St. Cloud, Minn. (60 miles above Coon Rapids) on the Elk River, and on the Run River. These three control about 15 000 sq miles of the drainage area, but, obviously, they do not intercept all the silt.

Furnish Reservoir, Near Pendleton, Ore.—By 1914, this reservoir had silted so badly that it became necessary to put flash-boards on the spillway in order to store sufficient water for the lands under the Furnish Ditch. The use of flash-boards was discontinued in 1930. The sluice-gate in the dam is opened as soon as the storage has been exhausted, permitting the river to flow through the Furnish Reservoir. This cuts a channel through the silt to the original gravel bed. Thus, a certain amount of desilting is done each year. The survey of 1930 is little more than an estimate by the Water Master. In 1932, the writer estimated the remaining storage capacity at about 600 acre-ft.

Lake Penick.—This reservoir stores water for Stamford, Tex. Of the drainage area, 30% is farming and 70% grazing land. The dam was begun in 1918. The run-off at the U. S. Geological Survey gauging station at Nugent, with a drainage area of 2 220 sq. miles (1924 to 1930), showed 680 200 acre-ft, or 111 000 acre-ft per yr. The maximum discharge was 11 500 cu ft per sec on May 20, 1928.

LaGrange Reservoir.—The diversion dam is for the Turlock and Modesto Irrigation Districts, near LaGrange, Calif. Surveys for silt content have been made as shown in Table 2(*g*). The Don Pedro Dam completed in 1923 is 6 miles up stream. When its spillway was first used much river débris was washed into the LaGrange Reservoir. The maximum recorded discharge was 38 100 cu ft per sec on March 25, 1928.

---

[8] H. R. Doc. No. 964, 63d Cong., 2d Session.

Buckhorn Reservoir, Near Loveland, Colo.—No records of stream flow have been kept. The reservoir had a capacity of 1 191 acre-ft upon completion in 1907. In 1925, surveys were made for increasing its capacity when it was found that the storage capacity had been reduced to 626 acre-ft by silt. The maximum flood of 10 500 cu ft per sec occurred on June 15, 1923 (61*a*).

Aswan Dam and Reservoir, Egypt.—The first dam was built to store water to a reservoir level (R. L.) of 106.0 m, with a capacity of 865 000 acre-ft. It was completed in 1902. No spillway was provided, but the dam has 180 sluice-gates to pass a maximum flood of 500 000 cu ft per sec. The dam was raised beginning in 1907 and completed in December, 1912, for storage to R. L. 113.0 m, providing a capacity of 1 970 000 acre-ft. A contract was let in 1929 to raise the dam again, this time to store water to R. L. 122.0 m, for which the capacity will be 4 400 000 acre-ft. The average annual flow of the Nile at Aswan (1912 to 1927) was 90 000 cu ft per sec, the maximum being 500 000 cu ft per sec.

Burrinjuck Reservoir.—Water for Murrumbidgee irrigation areas, in New South Wales, is stored in this reservoir. Construction was begun in 1908, and was completed by 1920. The spillway crest is at R. L. 1 180. The silt deposits were deduced from regular samplings above slack water, 1910 to 1916, and above slack water and below the dam, 1917 to 1924.

Dhukwan Reservoir.—This reservoir is above the mouth of Jamni River near Jhansi, United Provinces, India. The drainage area is without snow storage, and the silt deposits were estimated.

Pericha Reservoir.—This is 30 miles below the mouth of Jamni River and 35 miles below Dhukwan Reservoir. Silt deposits are reported to be negligible. The reason for silting in Dhukwan Reservoir and not in this reservoir could not be obtained. Silt interception by Dhukwan Reservoir does not fully explain this phenomenon, since it is 23 years old and has lost one-fourth of its capacity, while Pericha Reservoir has lost none in 48 years.

Habra Reservoir, in Algeria.—The dam broke in 1881 and all the silt was sluiced out. The reservoir was put in service again in 1885. During later years sluicing has been resorted to periodically. It is estimated that 4 900 acre-ft of silt have thus been sluiced out, so that the actual silt deposited should be increased by that amount. The river carries approximately 1% of silt by weight per annum.

Helena Reservoir.—The domestic water supply for Perth, Western Australia, is furnished by this reservoir. Surveys were made in 1913, 1920, and 1930. The stream flow into the reservoir from 1900 to 1930 registered a maximum per year of 151 000 acre-ft, and a minimum of 1 190 acre-ft.

Hamiz Reservoir, in Algeria.—Periodic sluicing was begun in 1901; 23% of the total water supply is used in sluicing out silt. No part of the silt deposited prior to 1901 has been removed but further loss of capacity has been prevented.

SEDIMENTATION PROCESSES

When a stream carrying a load of sediment into a reservoir meets the quiet waters of the reservoir its velocity is destroyed and its load of silt is deposited, forming a delta. In delta building the material is sorted as it is deposited. The finer material is carried far out into the reservoir and spread over the bottom. This part of the delta consists of the suspended load of the stream, sorted from coarse to fine and spread over a fan-shaped area the apex of which is at the mouth of the stream. For distinction this part of the delta is called the bottom-set bed.

Superimposed on this is the stream's bed load deposited over a fan-shaped area, and called the foreset bed. These deposits are also sorted, the coarser material settling first. The foreset beds are deposited in layers or strata normally inclined to the horizontal at the slope of repose of the material in its saturated condition ((81) (82)). These strata vary in thickness and in inclination with every variation of the stream's bed load and rate of flow.

The process of building the foreset beds is somewhat analogous to that of building road grades by continually dumping material on the advancing face. If the advancing face were fan-shaped and each carload was of different material in size, hue, and condition of saturation, a faint picture of the process of laying down a typical foreset bed may be had.

The top surface of the typical foreset bed is fairly level provided the water surface of the reservoir remains constant. On top of this is deposited the suspended load of the stream in the same manner that the original bottom-set beds were formed, except these deposits on top are of the coarser suspended material. This part of the delta is called the top-set bed. The finer suspended material is carried beyond the foreset bed and deposited as bottom-set bed in advance of the inclined strata of the foreset bed.

As the river flows over the top of the foreset bed, it may form ripples, dunes, and anti-dunes. Often the top-set beds are superimposed over these dunes and ripples, preserving them intact.

If the lake level varies periodically, but with sufficient time for deltaic deposits to be made at each level, the delta is formed in benches. Of such would be those in certain natural lakes the levels of which vary only with cyclic weather changes, as, for example, Great Salt Lake. When the level varies seasonally, such as is the case with most artificial reservoirs that may be emptied and filled one or more times each year, the delta soon loses its typical characteristics.

Variability of stream regimen, variability of reservoir levels, and variability of materials transported, introduce great complexities. Deposits at one level are cut through at a lower level and re-deposited farther out;

waves re-sort and flatten the slopes. The net result of these complex and interlocking processes may cause the deltaic shore to become a well-graded composite of coarse and fine material of considerably greater density than would be found in either of the delta beds in their idealistic state.

Where the reservoir capacity is small compared to the annual inflow, it may happen that a considerable part of the suspended load is carried through the reservoir and only the bed load is deposited. This is evidenced on many streams where the space above dams has been completely filled with coarse gravel and cobbles.

A sediment-carrying stream in a valley builds its bed and banks higher than the surrounding land. Alluvial valleys normally slope away from the stream channel. As the banks become higher the stream slope is reduced until finally a flood overtops and cuts through them and the river forms a new channel. The ends of the old channel soon become closed by silting and, thereafter, it stands as a lake until it is slowly filled by sediments from overflows and wind-borne materials.

A dam across a stream bed not only induces filling the slack-water space above it, but induces the deposition of river débris a long distance up stream. Fig. 3 is a profile of Bear Creek near Colfax, Calif., before and after the construction of a débris barrier. This comparatively low dam had the effect of withholding an enormous volume of coarse river débris from passing to the lower lands. This serves to illustrate an extreme case of aggrading a stream bed where only coarse sand, gravel, and boulders are concerned.

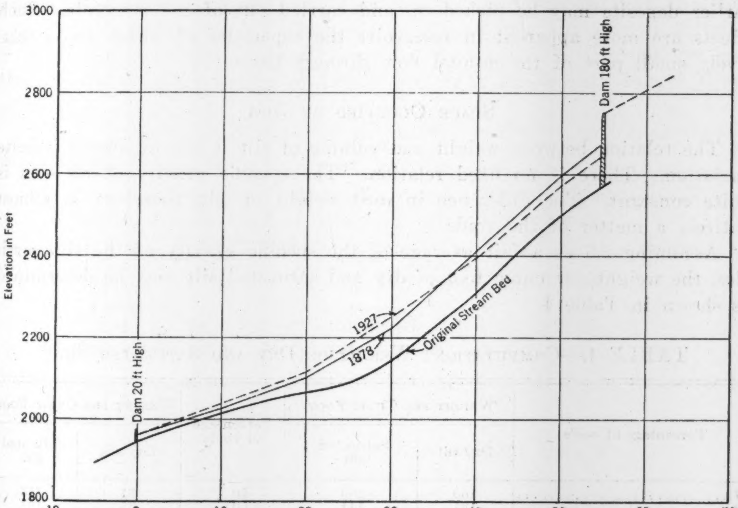

FIG. 3.—DÉBRIS BARRIER ON BEAR CREEK; CALIFORNIA DÉBRIS COMMISSION.

The Life of a Reservoir

A reservoir can only store water for subsequent use below its spillway level, or such other higher level as may be controlled by flash-boards or crest gates. The silt deposited below spillway level, therefore, robs the reservoir of that much water-holding capacity. Ultimately, a reservoir on a silt-laden stream will fill up to the spillway level, leaving only a meandering stream channel on the alluvial plane made by these deposits.

Table 1 shows the average rate of silt deposition per annum. The useful life of a reservoir is not the number of years obtained by dividing its original capacity by the deposition rate per year. Such generalizations are not permissible. The usefulness of a storage reservoir may be practically exhausted when its capacity has been reduced 50%, or some other substantial part of its original capacity. On the other hand, a reservoir for power purposes may still be useful after it is completely filled.

The rate of silt deposition diminishes as the reservoir fills. Deltas will form at the mouths of all tributaries. As the deposits fill the storage space a continually lessening volume of quiet water is available for deposition of the finer materials, with the result that a continually increasing part of the material entering is carried over the spillway. During extreme floods earlier deposits may be picked up and carried out of the reservoir. Such effects are more apparent in reservoirs the capacities of which are a relatively small part of the annual flow through them.

Space Occupied by Silt

The relation between weight and volume of silt is one of almost infinite variation. There is no fixed relation. The specific gravity of all silts is quite constant. The difference in unit weight of silt, therefore, is almost entirely a matter of the voids.

Assuming 2.6 as a fair average of the specific gravity of the silt particles, the weight per cubic foot of dry and saturated silt may be determined as shown in Table 4.

TABLE 4.—Computation: Weight of Dry and Saturated Silt

Percentage of voids	Weight per Cubic Foot		Percentage of voids	Weight per Cubic Foot	
	Dry silt	Saturated silt		Dry silt	Saturated silt
0	163	163	50	81	113
20	131	144	60	65	102
30	114	133	67.5	53	95
40	98	123	70	49	93
47.8	85	115	80	33	83

When silt is first deposited it is loose and flocculent, and the finer the silt the greater the volume it occupies. As it lies in place and more sediment is superimposed, it becomes more and more compact. Some have contended that the water pressure tends to compact the silt. Borings in silt deposits in California reservoirs (41) have shown: (*a*) That a definite water-table exists in the deposits commensurate with the water level of the reservoir; (*b*) that the deposits below the water-table are flocculent; and (*c*) that deposits do not shut off spring water inflow on the beds of reservoirs. Under such conditions the silt deposits are not consolidated by water pressure but by superimposed silt.

A most potent factor in compacting silt is exposure and consequent drying. The shrinkage of these deposits is evidenced by the cracks that form in a sun-dried exposure of fine silts.

Sands are not subject to such shrinkage. The amount of shrinkage, therefore, depends largely on the proportion of sand to clay and on the fineness of the clay. The more uniform the size of the particles the greater the voids and the less the specific weight. Deltaic deposits subject to wave action at all stages may become well graded from fine to coarse and, therefore, may be very dense.

These observations serve to explain why such disparity has been found in the volume-weight relation in various localities and by various investigators. Follett (48(*a*) (47) used a specific weight of 53 lb per cu ft for the Rio Grande silt. This was determined by selecting a single 3-in. cube from a sun-dried river bar. This sample was taken in 1904 and that weight has been used in all tables of the Rio Grande silt at San Marcial, N. Mex., since the beginning of the silt record in 1897. Humphreys and Abbot in 1861 used a weight of 120 lb per cu ft for the Mississippi River sediment.

Samples from exposed silt bars in various reservoirs in Texas showed the following (53):

Material	Dry weight, in pounds per cubic foot
Coarse silts at head of reservoir, probably consisted largely of bed load..........................	92
Fine silts from much the same location...........	85
Deposits on surface of silt beds near middle of reservoirs	55
Finest material from submerged deposits in old river channels of reservoirs..................	31

Seventeen samples from exposed silt beds of Elephant Butte Reservoir in 1916 yielded the data presented in Table 5.

TABLE 5.—SAMPLES FROM EXPOSED SILT BEDS OF ELEPHANT BUTTE RESERVOIR

Description	Maximum	Minimum	Average
Weight as taken, in pounds per cubic foot.......	124.3	96.7	104.7
Moisture, percentage	20.9	4.4	11.6
Weight dry, in pounds per cubic foot..........	101.2	87.9	92.3
Specific gravity........	2.66	2.59	2.64
Percentage of voids........	46.6	39.0	44.0

In India (20*a*) engineers have found that the silts of the Indus River, when wet, averaged 95 lb per cu ft and that they contained 45 lb of water and 50 lb of dry matter. Many determinations have been made of the specific weight of the silts of the Colorado River with greatly varying results (42*a*). A summary of these determinations is, as follows:

Location	Number of samples, mean of:	Dry weight, in pounds per cubic foot
Yuma, Ariz.	20	85.4
Laguna Dam	10	81.6
Bed silts: Imperial Canals, 1925	17	102
Bed silts: Imperial Canals, 1917–18	12	97
Gila River: Silt bars (80)	15	74.2
Deposits in Settling Basins of Imperial Valley Municipal Water Systems:		
El Centro, Calif.	12	45.2
Imperial, Calif.	12	37.0
Calexico, Calif.	10	37.7
Experimental settling basin at Parker City	5	57.5

The writer found the dry weight of all the sediment filtered from the daily samples from Coeur d'Alene River, Idaho, for more than a year (consisting largely of tailings from ore-reducing works) to be 50 lb per cu ft.

If it were not for the uncertain quantity of silt carried into reservoirs as bed load, it would be quite a simple matter to determine the space occupied by the suspended silt in streams flowing into reservoirs where the volume of deposits have been determined by careful capacity surveys. The comparison between suspended silt and deposits in the Elephant Butte Reservoir for determining the probable bed load of the Rio Grande (see heading, "The Bed Load"), shows the futility of this method unless the bed load can be determined by direct measurement in the stream.

As a result of their study of Colorado silts, Fortier and Blaney (42*b*) recommended the use of a specific weight of 62.5 lb per cu ft for suspended silts. This was a convenient figure because the percentage of silt by weight and by volume then becomes equal. For the space occupied in reservoirs on the Lower Colorado River, on account of the probable mixture of coarser bed load and suspended silt and also to allow for compacting by superimposed silt, they suggested the use of a specific weight of silt *in situ* in the reservoir of 85 lb per cu ft (42*c*). As a general average of the silt-bearing streams of Southwestern United States, these figures are consistent with all available data and can be used without great error.

STREAM TRANSPORTATION OF SILT

It has been estimated that the surface of the United States is being removed at the rate of 1 in. in 760 yr (3). At some time or other, the material removed is transported by streams. The total of solids removed is estimated at 783 000 000 tons per annum, of which 513 000 000 tons is suspended matter and 270 000 000 tons is dissolved solids.

Flowing water has the power to transport large quantities of finely divided material as a suspended load and also to drag other materials along its bed.

The higher the velocity and the more turbulent the stream, the greater the proportion of suspended load it is capable of carrying. When velocities slacken this material settles and the bed-load movement is arrested. Material remains in suspension by reason of the vertical components of currents and eddies within the water prism.

The shape of the silt particle has an important bearing on the facility with which it remains in suspension or settles to the bottom. The finer the material the slower it settles; rounded particles will settle much faster than flat scale-like particles; and, disk-like particles settle in still water (flat side down) with an oscillating motion requiring a long time.

The velocity of the water, the degree of fineness of the material, and the predominating shape of the particles are three correlated factors that determine the variant between the suspended load and the bed load of a stream.

On mountain streams the bottom load consists of boulders, cobble-stones, and coarse sand. The transporting of stones along a stream bed grinds them, ultimately, into material sufficiently fine to permit their being carried to the ocean as suspended load or as bottom load of slow-moving rivers. By far the greater part of the sediment transportation by streams occurs at the time of a flood. "Cloudbursts" on mountain streams may cause the movement of millions of tons of débris, from fine sands to boulders as large as houses. The waters of great rivers, at their mouths, seldom acquire sufficient velocities to move anything but sand and the smaller gravels.

There is no line of demarcation between suspended load and bed load. In the same stream a given material may be carried in suspension in one reach and as bed load in another. A flood will put in suspension large volumes of material formerly deposited on the bed and banks of the stream and start rolling a new bottom load of much heavier material. The transportation of detritus from mountain top to ocean bed is thus accomplished in stages by a series of spasmodic expenditures of stream energy interspersed with periods of quiescence.

Suspended Silt.—Table 6 gives a summary of the results of a large number of measurements to determine the suspended silt content of the streams of the world. The streams in the United States are arranged alphabetically by the major drainage basins. Tributary streams within those basins are arranged in order from head to mouth.

The Bed Load.—Little information is available as to the quantity of material transported as bed load. Humphreys and Abbot estimated the bed load at the mouth of the Mississippi River to be 11% of the suspended load. Fortier and Blaney place that of the Colorado River, at Yuma, Ariz., at 20% of the total load (42*d*). Follett stated that the bed load of the Rio Grande at San Marcial, N. Mex., "may amount to 25% of the silt carried in suspension."

Comparing the silt content of the Rio Grande during the years between capacity surveys (1916–1925) of Elephant Butte Reservoir, it is found that:

Total suspended silt passing San Marcial..= 217 000 000 tons
Total silt deposited in reservoir...........= 178 000 acre-ft.

* See Appendix.

Follett used a weight of 53 lb per cu ft for silt in the reservoir. If this specific weight is correct, 187 000 acre-ft of suspended silt passed San Marcial, which is more than was deposited in the reservoir. It is believed that only a negligible quantity of silt passed through the reservoir. On the basis of 65 lb per cu ft the volume of silt passing San Marcial amounted to 153 000 acre-ft of suspended silt, leaving 25 000 acre-ft for that brought in as bed load. This is 16% of the suspended load. It is thus seen that, in this case, the estimated volume of the bed load hinges on what specific weight is adopted for the reservoir deposits.

The writer investigated the silt carried and deposited by Coeur d'Alene River and from the resulting data made a rough estimate of the bed load. The investigation involved 9 miles of the river above Rose Lake, Idaho, in which twenty-six cross-sections were established and permanently marked. Surveys for silt content were made in May and November, 1921, and in March and July, 1922. Daily water samples were taken above and below this reach. Of the suspended load entering the reach, 75% was fine silt from ore-reduction works in the Coeur d'Alene Mining District and 25% was natural débris. The following data were obtained:

Period (May 13, 1921, to June 30, 1922), in days....	414
Suspended silt entering reach, in tons.............	444 600
Suspended silt leaving reach, in tons..............	363 100
Suspended silt deposited, in tons..................	81 500
Total deposits determined from cross-sections, in cubic yards	190 000

It is believed that 65 lb per cu ft will fairly represent the average specific weight of these deposits. Using this value, the bed load, in cubic yards, is found to be:

Total deposits, from soundings	190 000
Suspended load	93 000
Bed load	97 000

From this, it appears that the bed load and suspended load were each equal to about one-half the total. Although this work was done with care considerable uncertainty still remains. The volume assigned to bed load hinges on the specific weight assigned to the deposits. If instead of 65 lb per cu ft, a value of 80 lb is used, the bed load becomes 115 000 cu yd, or 60% of the deposits measured in place. If 50 lb is used, the bed load becomes 36% of the measured deposits.

Again, if the sampling gave results 10% too high at the upper end and 10% too low at the lower end, the entire volume deposited would have to be accounted for by bed load. If these errors were reversed the entire deposits would have come from the suspended load.

It would be better to express bed load as a percentage of the total load when possible. The foregoing data on bed load may be summarized in percentage of total débris transported, as follows:

	Suspended load	Bed load
Mississippi River, at mouth	90	10
Rio Grande, at San Marcial, N. Mex.	86	14
Colorado River, at Yuma, Ariz. (Fortier and Blaney)	80	20
Coeur d'Alene River, at Rose Lake, Idaho	49	51

The foregoing data are to be considered only as the roughest approximations; some are pure estimates, but they constitute the only data known to the writer. The difficulties of differentiating between bed load and suspended load are well illustrated in the case of the Coeur d'Alene River. Strictly, there is no line of demarcation--one merges indistinguishably into the other. As far as known no successful attempt has been made to measure the material transported in a river as bed load.

Laws of Silt Transportation.—Ordinary river flow is turbulent. The moving water prism contains many eddies and cross-currents. These serve to maintain the finer material in suspension and roll the coarser along the bed. The same material may alternate as bed load and suspended load. Bellasis (15*a*) defines suspended load as "silt", bed load as "drift"; and the weight of material per unit volume of water as the "charge".

There is an upper limit to the quantity of material a stream of given depth and velocity can transport. Such a charged stream will deposit silt at every reduction of velocity or decrease of turbulence and pick up more, if available, at every increase. A fully charged stream can not scour material from its channel, but its power of moving the drift or bed load is not impaired (15*b*).

About 1900, R. G. Kennedy, Executive Engineer, Public Works Department, Punjab, India, advanced the first formulas for transportation of silt by water as a result of his study of the Bari Doab Canal System. Kennedy presented the theory that there is a critical velocity for each depth that will neither scour nor permit deposits. His general formula is:

$$V_0 = C\, d^n \ldots\ldots\ldots\ldots (1)$$

in which, V_0 is the critical velocity that will neither drop nor pick up sediment; d is the depth of water; and C is a coefficient depending on the kind of silt.

The values of the constants in Equation (1) have been established experimentally (see Table 7).

TABLE 7.—CONSTANTS FOR SUBSTITUTION IN EQUATION (1)

C	n	Authority	Applicable to:
0.84	0.64	Kennedy	Upper Bari Doab Canal, Punjab, India.
0.91	0.57	Kennedy	Shwebo Canal, Burma.
0.67	0.55	Kennedy	Godaveri, Western Delta, Madras, India.
0.93	0.52	Kennedy	Kistna, Western Delta, Madras, India.
0.95	0.57	Lindley	Lower Chenal Canal, Punjab, India.
0.39	0.73	Ghaleb	Egypt.

Mr. Gerald Lacey presented the first general treatment of this complex subject in 1929 (57). Lacey[4] advances the theory that a stream flowing on its own alluvial plain possesses the following quite remarkable characteristics:

1.—The cross-section on straight reaches tends to become semi-elliptical.

2.—The parameter of the ellipse (ratio of the major to one-half the minor axis or surface width to maximum depth) depends solely on the character of the silt as regards fineness.

3.—For a given discharge, the wet perimeter is constant and independent of the character of silt.

4.—The silt factor bears a definite relation to the roughness coefficient in the Kutter and Manning formulas for discharge.

All attempts to apply the Kennedy formulas to the Imperial Valley conditions have proved unsuccessful (42*e*), and it appears that the Lacey formulas will prove equally disappointing.

It is scarcely possible that the complex laws of sediment transportation and deposit can be expressed for all kinds of river débris from dust to boulders as simply as Lacey has done it.

The writer is quite familiar with the Platte River in Nebraska. It flows on a deep bed of pure sand. The cross-section is anything but elliptical, and the channel conforms to no law except that of the mythical "Powder River" of the 91st Division of the American Expeditionary Force, whose slogan was: "It's a mile wide and an inch deep; we can swim it!"

---

[4] The original paper on file in Engineering Societies Library presents the Lacey formulas with considerable data and discussion.

Effect of Clarifying a Silt-Laden Stream.—This promises to become a most important phase of the silt problem. The Boulder Reservoir will discharge clear water for the first time in untold ages into an alluvial river channel. Moreover, the discharge will be much more uniform than now obtains. What effect this will have on the regimen of the river, and how it will affect diversions into canals will be watched with great interest. Changes in the river channel of a silt-laden stream, after its regimen as regards flow and silt content has been radically altered, have been exemplified in the Rio Grande below Elephant Butte Dam. In the 125-mile stretch below this storage dam there are four dams diverting water into six irrigation canals (6*b*). The changes in river regimen that have occurred since the storage reservoir began operating in 1915, are listed in Table 8.

TABLE 8.—CHANGES IN REGIMEN OF RIO GRANDE

Item No. (1)	Point of measurement (2)	Period of observation (3)	Years (4)	Before construction of Elephant Butte Dam (5)	After construction of Elephant Butte Dam (6)
		(*a*) MEAN ANNUAL RUN-OFF, IN ACRE-FEET

7	E. Paso, Tex.	June 12, 1905	...	23 700	...
8	El Paso, Tex.	Sept. 3, 1925	...	...	9 160
		(*c*) MEAN ANNUAL SILT CONTENT, IN TONS			
9	San Marcial, N. Mex.	1897–1914	18	22 800 000	...
10	San Marcial, N. Mex.	1915–1931	17	...	21 700 000
11	El Paso, Tex.	1906–1909	...	17 500 000	...
12	El Paso, Tex.	1916–1925	...	...	550 000

The general effect on the river channel has been to flatten the slope as indicated by cross-sections of the river taken since the storage began (1915 to 1925).

For the first 100 miles, the river has disposed of the débris from tributaries and, in addition, has taken about 480 acre-ft (2 100 000 cu yd) from its bed and banks and deposited them in the lower reaches. This degradation must continue until the river channel consists of a series of slopes between the diversion dams or other natural obstructions, just adequate to pass the mean-water and silt discharges under the new regimen that obtains under storage control.

On the Colorado River after the Boulder Reservoir is in operation a flattening of the river slope may be expected because large floods will be no more. Material will be picked up from the river channel by the clear water from the reservoir and deposited in the lower reaches. In time, the finer silts in the upper parts of the present channel may be carried entirely away, leaving only the coarser sands that may then move mostly as a bottom load in a fairly clear stream, except when it is muddied by floods on the tributaries.

Research on Silt Transportation.—The laws of silt transportation are known only imperfectly. They are now being made the subject of intensive research in both America and Europe. The first experimental study of the laws of sediment transportation with particular reference to bed load was undertaken by Gilbert (77) about 1914. His laboratory consisted of flumes with glass sides in which varying quantities and sizes of sands were introduced into streams of varying velocities. He observed transportation by saltation, the phenomena of sand ripples or dunes, and the conditions under which they migrated up stream or down stream. He developed equations for the tractive force to move sand mixtures. The work of Gilbert has not been followed up until recently.

Interest in this problem has again been stimulated and model experiments, together with mathematical studies of stream dynamics, are being made. MacDougall (71) is beginning where Gilbert left off, experimenting to determine the laws of bed-load transportation. Vogel (76), Matthes (75), and a staff of experimenters at the United States Waterways Laboratory at Vicksburg, Miss., are working extensively with models of particular reaches of the Mississippi and other rivers, studying the silt-transportation problems as regards shoaling, scouring, building of bars, effect of bends, etc.

The experimental and mathematical work by Rehbock, Prandtl (72), Hans Kramer, Assoc. M. Am. Soc. C. E., Bulle, and others in Germany, a mathematical review by O'Brien (74), and studies from the geological angle by Rubey (73) on the movement of débris as related to the conservation of energy in river systems, are all adding greatly to the sum total of the knowledge concerning the phenomena of sediment transportation and turbulent flow which are inseparably bound together.

These studies are incomplete, and discussion regarding the significance of observed phenomena is still rife.

CONTROL OF SILT

Except on certain small reservoirs for municipal or industrial purposes, it is generally impracticable to remove any substantial quantity of silt from reservoirs after it has been deposited. The most practicable remedy lies in preventing permanent deposits. Under certain circumstances this is quite possible. Some examples in which effective measures have been taken to prevent such permanent silt deposits will be cited.

The Aswan Dam is provided with sufficient sluice-gate capacity to pass the entire flood discharge of the Nile. These sluice-gates are opened at the beginning of the flood period, and the river flows through the reservoir practically as if no dam existed. During such flood periods, although the Nile is heavily charged with silt, no depositions occur in the reservoir. After the peak of the flood has passed, and the river begins to run clear, the sluice-gates are gradually closed and the reservoir is filled for use during the subsequent irrigation season. By this method of operation silting of the Aswan Reservoir has been so far, and probably will be, entirely avoided.

In Algeria, on the Habra and Hamiz Reservoirs, considerable success has been attained by opening sluice-gates of relatively small discharging capacity in the dams at the close of the irrigation season and allowing the stream to cut through the silt deposits, carrying out substantial quantities.

Bhatgurk Reservoir (5*c*) on the Yeluand River, in Bombay, India, completed in 1892, is provided with twenty under-sluices, each 80 sq ft in cross-section. The operations of these scouring sluices have no appreciable effect on silt already deposited, but having sufficient capacity to pass the average flood, the greater part of the silt is carried off while it is yet in suspension.

In the Zuñi Reservoir there were three 14-in. outlet gates in the tower, two of which became useless by silting. The outlet tunnel through the dam is 6 ft. in diameter. In 1931, a 4 by 6-ft sluice-gate was installed in the gate tower at Elevation 950. When first opened there immediately followed a flow of water and silt under a 40-ft head sufficient to fill the tunnel. From July 1, to October 15, 1931, 500 acre-ft (807 500 cu yd) of silt were sluiced out of this reservoir.

Silt Control on the Water-Shed.—Streams draining areas in arid climates, where fine sedimentary materials occur, are always silt laden. Many such streams are ephemeral; that is, they flow during storm periods only. Their valleys are of alluvial deposits that may be built up during long periods of years and then appear to suffer a fairly rapid degrading, the causes of which are complex and not fully understood. Among such streams are the Zuñi, Pecos, Puerco, Chaco, and Gila Rivers.

It is quite well established that a good growth of grasses is very effective in holding the soil. Where the precipitation is sufficient to maintain forests, extensive soil removal is prevented during ordinary amounts of precipitation. During heavy rains, causing extreme floods, neither grasses nor forests can prevent extensive erosion.

On the Zuñi River water-shed, silt control was begun in 1923 (40*i*). Nutria Creek was found to be supplying most of the silt, and systematic protective measures on this tributary were undertaken. Brush and rock checks were built across the main and tributary arroyos at critical points sufficiently close together to form a new and flatter gradient for the streams. At sharp bends and elsewhere at critical points rock and brush mattresses were constructed to prevent excessive cutting and consequent bank caving.

This work has been continued. Each year additional protective works have been built and the old structures maintained. Fig. 2 shows the silt deposits in Zuñi Reservoir. Note the diminution in the rate of silting after protective measures were undertaken in 1923.

The Rio Puerco is one of the main silt-bearing streams tributary to the Rio Grande above Elephant Butte Reservoir. This water-shed has been the subject of special study on behalf of the Middle Rio Grande Conservancy District (10). In former years, this river had a discontinuous channel, the valley floor having a goodly portion of broad, grassy or marshy areas over which moderate flood waters passed in thin sheets. In other places there was a definite channel, about 15 ft deep and 100 ft, or more, in width. About 1885, the river began a progressive degrading of its channel from its mouth up stream. An arroyo with many tributaries now exists well toward the head-waters. Surveys show that this main arroyo is 150 miles long and averages 28 ft in depth and 285 ft in width. The original channel had only about 12% of the volume of the present channel. These arroyos are being widened by caving of banks and transportation of the silt into the Rio Grande and on into Elephant Butte Reservoir. It has been estimated that during the 42 years prior to 1927 a total of 395 000 acre-ft of silt has been eroded from the valley floor of Rio Puerco and its tributary channels. This is an average of 9 400 acre-ft per yr and is nearly one-half the average deposits in Elephant Butte Reservoir. Protective measures have been planned, but to date have not been undertaken.

Excluding Silt from Canals.—The problem of preventing débris from entering canals diverting from silt-bearing streams has occupied the serious attention of engineers the world over.

On streams that run clear at ordinary stages, but carry a coarse bed load, the best solution has been found to construct the canal gates parallel to the shore of the stream and provide them with flash-board or over-flow gates so that the water taken into the canal is skimmed off the surface. If the water is raised by a dam, a sluice-gate is provided so that débris deposited in front of the gates can be sluiced away and passed on down the river whenever a surplus of water is available for sluicing.

On streams that carry considerable suspended silt in addition to bed load, settling basins have been used—located immediately below or in conjunction with the head-works, with provisions for periodically sluicing the deposits back into the river. One of the best examples of this method of silt control is afforded by the head-works of the Fort Laramie Canal, of the U. S. Bureau of Reclamation, at the Whalen Diversion Dam on the North Platte River, in Wyoming (6*d*).

All-American Canal.—On streams heavily laden with fine suspended silts, such as the Colorado River, desilting is a serious problem. On account of the slowness with which this silt settles even in still water, enormous settling basins are required. Studies are now (1934) under way for the head-works of the All-American Canal from the Lower Colorado River. The intake structure is planned to be located about 19 miles above Yuma, Ariz. Enormous desilting basins have been included in the preliminary designs.

S. L. Rothery, M. Am. Soc. C. E., has advanced (27) the theory that, in this stream, exclusion of the bed load from the canal up stream is of greater importance than exclusion of the suspended load.

The Laguna Dam, on the Colorado River, was completed in 1909. The head-works follow closely the design for silt-laden streams developed in India and Egypt. Three similar dams on the Nile River had been constructed during the fifteen years preceding the design of the Laguna Dam. The dam is 19 ft high, 4 800 ft long, and raises the water 10 ft at low water. It backs water about 10 miles up stream, creating a settling basin. This basin silted up soon after the dam was put in operation. At the ends of the dam a long sluice-way is provided which takes water from this basin. A long skimming weir with crest flash-boards in the land side of this sluice-way forms the head-gates proper, of the canal. The end of the sluice-way is provided with three large gates of sufficient capacity to pass 20 000 cu ft per sec. Fig. 4 is a general plan of the structure.

FIG. 4.—PLAN OF LAGUNA DAM.

Experiments on the efficiency of the desilting works at Laguna Dam during August and October, 1918, showed that the water in the main canal at the head contained 57% less silt than that of the river above the dam (42*f*).

Canals in India.—Much study and experimentation have been devoted to methods of preventing silts being taken into the large canal systems from the heavily silt-laden streams of India. In general, diversion is by means of a low dam or barrage. Several canals may head from one diversion dam and generally from both sides of the river.

A stream in alluvium consists of bends, straight reaches, and inflection points between bends. The latter are also called "crossings". At a bend the top flows toward the concave bank and the bottom filaments flow toward the convex bank. The effect of this phenomenon is to cause the bed load to be drawn to the convex side of the bend. A canal, therefore, that heads on the concave side of a bend will receive less bed load than one heading on the other side.

The Indian practice is to construct a dividing wall extending up stream from the barrage and reaching above high water. This wall forms an approach channel to the canal intake. Fig. 5 shows a plan of the Ferozepore Barrage, on Sutlej River. Two dividing walls are provided. Under-sluices are sometimes placed in the dividing wall opposite the canal gates in order to draw the bed load of sand away from the intake.

Passing Silt on to the Land.—Silt that passes into the canal at the headworks must be cleaned every year from the canal system unless the distributaries are designed and constructed to carry the silt through them to the land irrigated, or to discharge it through waste channels. The laws of silt transportation have already been discussed. The practice in India appears to be to pass as much silt as possible on to the lands. Suffice it to state, thus far, in the United States, the behavior of canals is so erratic and the laws of silt transportation are so imperfectly understood, that no one has succeeded in designing a canal system for the Western silt-laden rivers that makes it possible to pass the silt on to the lands. Certain reaches of certain canals have been observed to be practically non-silting and non-scouring for flows near the maximum. For lower flows that must be carried during a part of the season, however, extensive silting inevitably results.

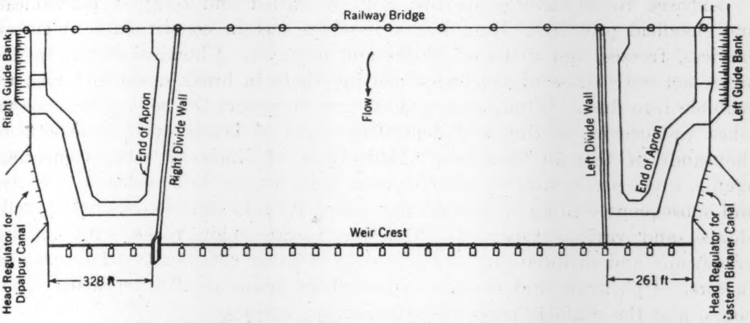

FIG. 5.—FEROZEPORE BARRAGE, SUTLEJ RIVER, INDIA.

The Imperial Irrigation District occupies a part of the delta of the Colorado River. The main canal diverts from the river at the Rockwood Heading, a short distance above the International Boundary. This structure is of concrete, built parallel to the river bank. It consists of seventy-five openings controlled by flash-boards, by which the river surface may be skimmed, thus excluding a part at least of the heavier material. There is no dam except a low brush-and-rock affair built during some years in the low-water period. Silt that enters the canal is removed by dredging. The canal diverts between 2 000 and 6 000 cu ft per sec from the river during the irrigation season. From the head-works of this canal 15 000 000 cu yd of silt were removed by dredging during the three seasons, 1918–1920 (50*b*).

The suspended silt found throughout this Canal System varies from 2 to 8 per 1 000 by weight during the height of the irrigation season. Practically all the suspended silt is so fine that it will pass a 200-mesh sieve, and the greater part passes a 300-mesh sieve (42*g*). A velocity of $\frac{2}{3}$ ft per sec will maintain this silt in suspension.

Experience in the Imperial Valley seems to prove that it would be cheaper to remove the silt from the Canal System by machinery than to pass it to, and care for it on, the cropped lands (42*g*). The quantity of silt removed from the Canal System by machinery is approximately 4 250 000 cu yd per annum (58), of which one-third is taken out by dredges at the head-works. This is a large quantity of material to handle each year, but it is a relatively small part of the amount taken into the system. In 1914, 30 000 000 cu yd of sediment were taken in at the Hanlon Head-Gate. About 4 000 000 cu yd were removed by machinery from the System, leaving 26 000 000 cu yd to be carried on to the land or passed through wasteways. It is impossible to hold the silt in the Canal System from which it could be dredged cheaply.

The disposal of silt in irrigation systems supplied by the Colorado River and similar silt-laden streams constitutes a serious problem, for which no adequate solution has as yet been found.

ORIGIN OF SILT

Exposed rocks disintegrate into soil by varied and complex mechanical and chemical processes. Rain water dissolves certain constituents; it enters crevices, freezes, and spalls off blocks and particles. Chemical agents in the air re-act with those of the rocks, causing them to break down and even to crumble into dust. Wind, rain, and streams transport the soils thus made to lakes and oceans, sorting and depositing them in layers or beds sometimes thousands of feet in thickness. Infiltration of limes or other cementing agents, great pressure from superimposed beds, intense heat, volcanic activity, and subsequent cooling re-convert these deposits into limestones, shales, sandstones, and various types of crystalline metamorphic rocks with infinite gradations and modulations as effected by a great complexity of forces and factors. Upheavals and erosion expose them again to disintegrating influences, and the cycle is repeated with infinite variety.

Sedimentation is that phase of the geological cycle involving water transportation and deposition. Every rill and river performs its allotted part in this process. Lakes and valleys are filled, great deltas extend fan-like into oceans, creating alluvial plains. The densely populous plains of the Nile, Ganges, Mississippi, and Yellow Rivers are the results of such sedimentation processes.

Most streams run fairly clear at low stages, but while so doing they may move quantities of sand and detritus along their beds. At high stages a suspended silt load develops and the stream is said to run "'muddy". At every slackening of the velocity both suspended load and bed-carried material are deposited, forming bars, berms, deltas, valleys, and alluvial plains.

Some rivers carry a suspended load at all times. Generally, these rivers drain arid or semi-arid areas. It appears that in areas of abundant precipitation the streams are capable of carrying off all the detritus resulting from rock disintegration as fast as it accumulates. The result is that the streams run clear except at times of flood. On arid areas the débris from disintegration may remain in place for many years until an unusual rainfall (cloudburst) occurs, when great quantities of silts are transported. If the drainage area is large enough and has many tributaries, the "unusual" rainfall is almost continuously occurring successively in some places. This keeps the main stream continually supplied with an abundance of silt, which it must carry at all stages. Of such, are the water-sheds of the Rio Grande, the Colorado, Missouri, Colorado River of Texas, Yellow, and Indus Rivers.

The character of the drainage area and its vegetable covering are all-important factors. If the rocks of the area are sedimentaries, such as sandstone, clays, and shales, disintegration processes produce large quantities of fine soils. If forests exist this soil is effectively held in place against ordinary rains, but the forest rapidly loses its efficacy to prevent erosion in times of intense rainfall. If the area is too dry for forests, the soil may still be held effectively by substantial growths of grasses and small brush. If too arid for small growth, the soil lies at the mercy of every shower.

Bank cutting is a fruitful source of sediment. The process of moving soil from the mountains to the sea consists of an infinite number of starts and stops. A bar is formed during this flood that may not be moved for many years. An alluvial valley is built up during centuries of sedimentation and then deleted under a new set of cultural or climatic conditions. Alluvial streams build their beds and banks higher than the surrounding plain, a process which, however, can not continue indefinitely. A flood breaks the banks and the river finds a new channel, cutting out the deposits it had itself laid down in earlier years. The Yellow River built up its channel until the water surface was 25 ft above its plain. During the floods of 1851 to 1853 it broke its bank, inundated 50 000 sq miles of cultivated valley, snuffed out a million lives, and found a new mouth 500 miles to the north of its former outlet. This river of mud is often referred to as "China's Sorrow" (12*b*).

The Missouri River is always muddy in its lower reaches. Its Indian name means "Big Muddy". It receives much silt from the clay beds of the Bad Lands of South Dakota and from the enormous areas of shale in Montana and elsewhere in its upper valley, and, in addition, takes continuous toll from its bank through the alluvial plain through which it flows.

The Colorado River becomes a silt-laden stream after it passes into Utah. Much of its drainage area is so arid it is quite void of vegetation. Floods from local rains occur in great diversity on its many ephemeral tributaries that keep the main stream loaded with silt. These characteristics also apply in varying degrees to the Rio Grande, the Colorado River of Texas, the Brazos, Trinity, and many other Southwestern streams.

The Yellow River in Northern China carries nearly twice as much silt per annum as the Mississippi. Its drainage area is largely covered with loess, a yellowish, friable, wind-blown deposit of fine sands and dust-like soil that is carried away with every rainfall, keeping the streams continually surcharged. Its name and that of the Yellow Sea into which it flows is derived from the color this loess gives to the water.

In India, all the great rivers are silt-laden streams. Between the Himalayas and the Indian Peninsula lie the great alluvial plains watered by three great river systems. The Indus, with its principal tributary, the Sutlej, waters the western portion; the eastern portion is drained by the Brahmaputra; while between them lies the Ganges.

The Indus Valley is quite arid and is covered with fine alluvial silts and wind-blown sands. The Ganges and Brahmaputra areas have a seasonal climate. Parts of these areas are seasonally dry; irrigation is profitable. From these areas enormous quantities of silts are supplied to the rivers so that the streams flow on broad alluvial deposits, which although about 2 000 ft thick, are nevertheless geologically recent.

The Nile is perhaps the most famous river of history. The silts deposited on the lands at the time of its annual inundation have made the fertile plains of Lower Egypt. The Nile carries annually 95 000 000 tons of silt, of which 30 000 000 remains on the land and 65 000 000 is carried into the Mediterranean Sea. At ordinary stages, the Upper Nile is fairly clear, but in flood periods it is of a chocolate color from the brown soils of the Abyssinian plateaus brought in by the Sobat, Blue Nile, and Atbara, which streams are the chief sources of the Nile floods.

The Rio Puerco drains 5 700 sq miles of Western New Mexico. The name means "dirty river". It and its neighbouring stream, Rio Salado, are sources of abundant quantities of silt in the Rio Grande and pour these silts into that stream above Elephant Butte Reservoir. Because of this fact Rio Puerco has been the subject of special study from a geological standpoint by Kirk Bryan, Professor of Geology, Harvard University, and from an engineering point of view by Mr. George M. Post (10). Because their report contains data that are essentially applicable to many other streams, they will be presented as quite typical of the silt-bearing ephemeral streams of the arid Southwest.

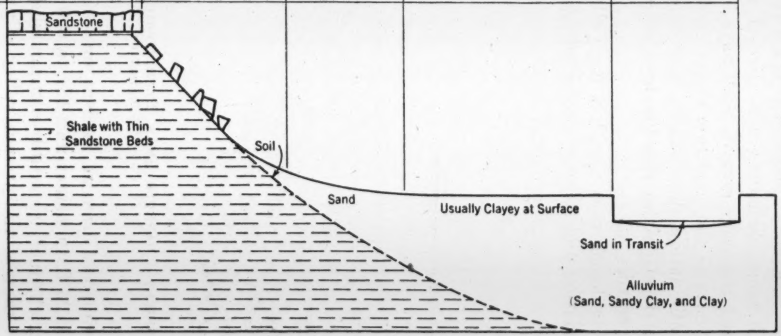
The silts move only during floods— a quick rush of muddy water down a dry channel immediately following a rain. Rio Puerco has always carried large quantities of silt into the Rio Grande, but this quantity has been increased materially in recent years. The investigation was prompted by the hope and belief that the channel would be rehabilitated and the silt charge greatly reduced.

When first known, the main stream and its tributaries were in a process of alluviation. The valleys were plains over which muddy floods spread out or flowed in discontinuous channels. In places, these channels may have been 10 to 20 ft deep and 100 ft, or more, wide, but they were interspersed by broad, flat, marshy areas over which the water spread in sheets. About 1885, a new arroyo began to form at the mouth and to cut up stream, until the channel is now continuous for 150 miles and averages 28 ft in depth and 285 ft in width.

In order better to understand this process, Figs. 6 and 7 have been reproduced (10), showing how the alluvial valley was formed and how degradation now appears to be progressing in the Valley of Rio Puerco.

The silts come mainly from the disintegration of Cretaceous rocks that cover about one-half the drainage area. The characteristic topography of the silt-producing areas consists of mesas underlaid by sandstone lying between broad valleys eroded in the shales (Fig. 6). The sandstone cliff is undermined by the more rapidly eroding shale and breaks off along joint planes. These pieces weather into sands, while the shale base forms clays. The valleys become filled with fine argillaceous sands that are eroded easily unless held by grass sod or other vegetation. Gullies are formed on the steep hillsides that end in deltaic fans formed by silts deposited at the valley floor. These deposits form cracks when dried, creating vertical joint planes in the mass. When such deposits form the banks of a stream, they

Topographic Divisions	Mesa	Cliff Edge	Hill Slope	Alluvial Fan	Valley Floor	Channel Trench (Arroyo)
Vegetation	Pine, Juniper Piñon		Juniper, Grass	Grass and Sage	Grass, Weeds, Greasewood	Usually Barren Grass and Weeds
Rate of Weathering	Slow	Rapid	Rapid	No Importance	No Importance	
Rate of Run-off	Feeble	Rapid	Rapid	Small Except from Heavy Rains	Rapid	
Rate of Silt Production	Moderate	Moderate	Moderate	Small Unless Gullied	Small Unless Gullied	Excessive, Due to Lateral Erosion



Sandstone
Shale with Thin Sandstone Beds
Soil
Sand
Usually Clayey at Surface
Sand in Transit
Alluvium
(Sand, Sandy Clay, and Clay)

(*d*) Conditions of Decreasing Erosion When A Large Part of the Alluvium Shall have been Removed

FIG. 7.—DEMONSTRATING HOW AN ALLUVIAL VALLEY MAY BE DEGRADED.

are easily undermined; the banks cave off in blocks, crumble, and become the suspended load of the stream.

Rio Puerco began degrading its valley floor about fifty years ago. Fig. 7 shows the successive events as they have been pieced together by historical inquiry and geological evidence. The silt derived from the valley walls was carried over the surface and on down stream through discontinuous channels, intermittently by the floods. This condition is shown in Fig. 7(*a*). With the cutting of the arroyos, the present period of abnormal erosion or degrading process began (Fig. 7(*b*)). The rate of silt production passes through a cycle. When the main arroyo is narrow and increasing in length up stream, the rate of silt production is increasing. When it becomes a continuous channel the widening process begins (Fig. 7(*c*)). At this stage, the rate of silt production has reached a maximum. When the channel becomes so wide that the floods only touch its sides lightly or intermittently, bank caving and consequent silt production begin to diminish.

A time will come when the entire slice of alluvium above the new grades of the main and tributary arroyos shall have been removed (Fig. 7(*d*)). The valley then reverts to the condition shown in Fig. 7(*a*), but at a lower level. A process of alluviation then sets in that tends to build up the valley floor to some higher level. After this has been accomplished, the cycle of degrading will be repeated.

Abundant evidences were found in the Valley of the Rio Puerco of earlier cycles of alluviation and subsequent degrading. Fig 8 is a map of the present channel superimposed over an ancient one. The present arroyo has nearly vertical banks, 25 ft in height and 180 to 500 ft apart. The outcrops of the buried ancient channel are readily distinguishable because its filling is lighter in color than that of the present valley alluvium. The bed of the ancient channel was about the same level as the present channel and varied from 75 to 220 ft in width.

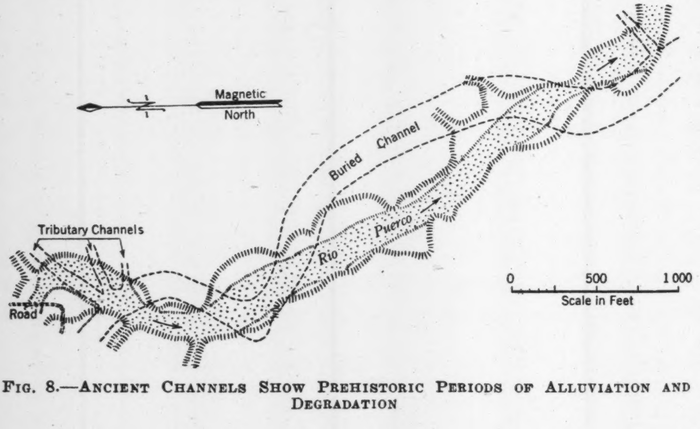

FIG. 8.—ANCIENT CHANNELS SHOW PREHISTORIC PERIODS OF ALLUVIATION AND DEGRADATION

Traces of other channels were found, but not mapped. These buried channels represent a period of erosion and degrading similar to that going on at present. Each was followed by a period of alluviation, that completely obliterated traces of old arroyos and in general made a plain of the valley floor over which the flood waters could spread and continue the upbuilding of the valley.

Another famous example of a cycle of alluviation and degrading has been found in the Rio Chaco (10*a*), (78). At Pueblo Bonito, an arroyo from 150 to 450 ft wide and 25 to 30 ft deep exists at present similar in all respects to the one on Rio Puerco. This arroyo has been cut since 1860. Pottery and charcoal, to depths of 20 ft, or more, are found in the valley alluvium showing that this alluviation occurred during its occupancy by pre-historic peoples. After Pueblo Bonito and other large pueblos were built and occupied, an arroyo was cut through the valley floor and later filled by alluviation to its original level. Where this buried channel outcrops in the walls of the present arroyo, pottery of very recent occupancy is found, while at similar depths in the main valley fill only pottery of much earlier periods has been discovered.

This ancient arroyo does not coincide with the present one, but is crossed, touched, and re-crossed by it. The ancient channel may be traced for about five miles. It tells the same story of periods of degrading followed by periods of alluviation.

These ancient peoples probably subsisted largely by "flood-water farming". When the ancient arroyo was cut in the valley about the end of the Great Pueblo period, it rendered such farming methods impossible. This has been assigned by Professor Bryan as a possible reason for the abandonment of these Indian villages (79*a*). A subsequent period of alluviation filled this arroyo and probably permitted re-occupancy. The present period constitutes another cycle of degradation.

The Zuñi River has been the subject of a study similar to that of the Rio Puerco (10*c*). It is an ephemeral stream, carrying only flood waters and large quantities of silt. The drainage basin consists mainly of plateaus and mesas underlaid by Cretaceous sandstone and shale. Like the Rio Puerco its silt is derived mainly from the erosion of the banks of arroyos cut in the valley fill. This stream is also undergoing a process of degrading its valley floor.

Ancient channels have been found in the Valley of Zuñi River, also, that attest to earlier periods of alluviation and degradation. Fig. 9 is a sketch of such an ancient channel exposed in the high banks of Nutria Creek.

Causes of Valley Degradation.—No complete explanation for these cycles of alluviation and degrading has as yet been found. The potent factors are deep seated and are quite certainly beyond Man's power to alleviate to any great extent, except in certain favored situations. The cause is probably to be found in climatic influences, and the physics of sedimentation as applied to the moulding of stream valleys. During a period of alluviation the slope of the valley is flattened. In time, it becomes too flat for the stream to carry its normal flood waters. A period of channel cutting ensues. This process of degradation is carried beyond the balance point, and a period of alluviation sets in. Thus, valley building appears to be an endless succession of periods of alluviation and degradation.

DISCUSSION

Harry G. Nickle,[6] Jun. Am. Soc. C. E. (by letter).—In gathering data from many sources all over the world, Mr. Stevens has shown clearly the many interrelated questions involved in the silt problem, and the need for continued research in these subjects. As the population continues to increase and it becomes necessary to conserve more fully the water resources of the United States, the problems discussed in this paper and the need for more data concerning them will become increasingly important.

Of immediate interest to those in charge of the construction of reservoirs along streams, especially in the more arid sections of the country, are the quantities of silt to be carried by streams into any proposed reservoirs and the conditions and volume of deposit of that silt in the reservoirs under various conditions of operation.

The quantity of suspended material carried by a stream can be determined with sufficient accuracy, by regular samplings, preferably taken daily, and such sampling stations should be established on all silt-laden streams which have possible reservoir sites so that as long a period of record may be obtained as possible before each reservoir is constructed. The quantity of bed-load rolled along the the bottom at any location is a more difficult problem to determine and much research remains in order to perfect a means of measuring this bed-load. The bed-load should be measured, if possible, at the same stations as the suspended silt and throughout the same period of time. The conditions and volume of silt deposits in reservoirs under different conditions of operation are known to vary widely, and much research is still necessary in this field—especially through studies and surveys of existing silt deposits—before complete information will be available. In this regard, in each reservoir investigated, a detailed study should be made of the contributing watershed, including its geology, topography, vegetal cover, and other pertinent characteristics.

Mr. Stevens states that the rate of silt deposition diminishes as the reservoir fills, due to a continually lessening volume of quiet water, with the result that more silt is carried over the spillway, and also that during extreme floods earlier deposits may be picked up and carried out of the reservoir. This, of course, is true ultimately of all reservoirs. However, in any large reservoir in which the capacity above the spillway or sluice-way is large compared with the inflow, it will generally be many years before such an effect will occur to any appreciable extent. O. A. Faris, M. Am. Soc. C. E., states[7]:

> "Suspended silt settles to the reservoir bottom soon after entering the slack water and, having a greater specific gravity than water, flows, in the form of liquid mud, down the slopes into depressions and along the main channel until blocked by the dam. Owing to its greater density, silt-charged water entering a reservoir partly filled with clear water does not mingle with

[7] "The Silt Load of Texas Streams," by Orville A. Faris, M. Am. Soc. C. E., *Technical Bulletin No. 382*, U. S. Dept. of Agriculture, 1933.

the clear, but forces it down stream toward the dam. No suspended silt is carried through the reservoir and over the spillway until all of the clear water has been discharged."

On the other hand, in small reservoirs (those in which the capacity is relatively small compared to the inflow during floods and in which stream conditions prevail during floods rather than reservoir conditions), many different effects may occur. For instance, one flood may deposit large quantities of material and a later one may clean large volumes of this material from the reservoir; or in other cases a slope may be built on the upper side of the spillway so that heavy materials are rolled up and over it, as finer materials are carried over in suspension. The exact behavior of floods through these smaller reservoirs, the deposition and picking up of material in them, and the quantity of material carried over the spillways are subjects that could be investigated more thoroughly, because they are constantly being discussed when new small reservoirs are proposed or built.

When the water level is subject to fluctuations the rate at which silt is deposited in a reservoir also diminishes, in general. The reservoir becomes filled because a greater area of the deposited silt is exposed during the fluctuations of water surface, and, consequently, these later deposits are more dense. The increase in the density of these later deposits depends not only on the frequency of wetting and drying, but also on the nature of the particles of which the silt is composed.

Since the summer of 1924, the silt problem in Texas has been studied by the Bureau of Agricultural Engineering of the U. S. Department of Agriculture (the Division of Agricultural Engineering of the Bureau of Public Roads prior to July 1, 1934), in co-operation with the Texas Board of Water Engineers.

Tens of thousands of samples of the water have been taken from the principal streams of Texas at twenty-three regular sampling stations, and the quantity of silt has been determined at these stations over varying periods of time. Miscellaneous samples have also been taken at various other locations throughout the State. Conditions of silt deposits in several of the reservoirs of the State have been studied in detail, and other phases of the silt problem have been investigated, including the quantity of bed-load carried by streams, the distribution of the silt throughout the cross-section of the stream, the relationship of the quantity of silt to the velocity, and the size and character of the particles composing the silt deposits, both in the reservoirs and along the stream channels. This co-operative work was under the direction of the late Robert Grier Hemphill, Assoc. M. Am. Soc. C. E., until his death in 1930; then under that of Mr. Faris until the end of 1933; and, under the writer, since April, 1934.

The results of this silt investigation to the end of the year 1930 were published in September, 1933.[7] Only a small part of the results of this intensive silt investigation in Texas have been given in Mr. Stevens' paper.

In September, 1925, at a time of low stage, a silt survey was made of Medina Reservoir, on the Medina River, about 35 miles northwest of San Antonio, Tex. The drainage area of this reservoir is 587 sq miles, the larger part of which is brush-covered grazing land, with a range in elevation of from 1 000 to 2 500 ft above sea level, and with an average rainfall of 29 in. The storage capacity at the elevation of the spillway crest was 254 000 acre-ft when the reservoir was constructed. After thirteen years of operation, in 1925, this reservoir contained 2 692 acre-ft of deposited silt, or only 1.06% of the total capacity of the reservoir when constructed. This represents a yearly average of 207 acre-ft, or 0.35 acre-ft per sq mile of water-shed per year. This deposited material had an average dry weight of 30 lb per cu ft when the survey was made in 1925, but five years later, owing to exposure to the sun and atmosphere at various times during the five years, the average dry weight of the material in place was estimated to be 63.6 lb per cu ft. In other words, the 2 692 acre-ft of deposited silt measured in 1925 had shrunk to only 1 270 acre-ft in 1930, or only 0.50% of the total capacity of the reservoir when constructed.

Measurements of the average weight of dried silt per cubic foot of material in place, taken at several reservoirs, vary from 18 to 37 lb per cu ft, when the deposited material has been under water at all times, to 85 or 100 lb per cu ft, or even higher, at locations where the deposits were subject to alternate wetting and drying, these values differing in each case not only due to different conditions of operation of the reservoirs, but also to the varying gradations and sizes of the particles of which the deposits are composed. Due to varying characteristics of large drainage areas and the varying conditions under which reservoirs are operated, it has been impossible to set a definite value for the dry weight of the deposited silt. However, after considering all factors entering into the problems, including the fact that an indeterminable quantity of vegetable matter deposits also and lasts indefinitely, a value of 70 lb per cu ft of material in place was chosen as an average ultimate figure for reservoirs in which silt deposits are subject to alternate wetting and drying.

Samples of dried silt from reservoir deposits had an average specific gravity of about 2.65, whereas samples taken from suspension and from which vegetable matter was excluded, had an average specific gravity of 2.73. Mechanical analyses of various samples of suspended silt from the streams of Texas showed on the average more than 97% passing the No. 300 sieve. Of the liquid mud taken from the Medina Reservoir, 99.5% passed the No. 300 sieve; and of the silt samples taken of the deposited material at Lake Worth, only one showed greater than 0.2% retained on the No. 300 sieve.

No direct relation was found between the volume of suspended silt carried and the velocity of the stream. However, in the cases considered, capacity loads were not even approached and the quantity carried was a function of loading only.

Table 9 gives records (which are similar to, but which are not included in, Table 6 of Mr. Stevens' paper) of silt carried by the streams at the several silt-sampling stations to the end of 1930. At several of these stations, especially those in the upper reaches of the Brazos River water-shed, the flow is intermittent, sometimes many days or even several months elapsing without any flow past some of these stations.

E. W. LANE,[8] M. AM. SOC. C. E. (by letter).—As the development of water resources for water supply, water power, irrigation, and navigation is becoming more thorough, and the control of floods of streams in the United States is growing more urgent, the silt problem which Mr. Stevens so interestingly describes, is increasing in importance yearly; in the future, no doubt, it will be even more vital. In order to find adequate solutions for the present and prospective silt problems, a more complete development of the governing laws is necessary. At present, this science is in an undeveloped state. Although much progress has been made, the problem is very complex, due to the large number of variables involved, and much remains to be accomplished before a satisfactory science will have been developed.

Like other phases of hydraulic engineering, present knowledge of the mechanics of the solids load of streams has been a gradual growth, with its beginning many years ago. Probably the first scientific approach was made by Guglielmini near the end of the Seventeenth Century. He developed laws governing fluvial phenomena, in connection with the control of the Po River in Italy. The problem first assumed importance in the United States in connection with the controversies which arose over the control of the floods of the Mississippi River and the construction of jetties for navigation improvement at its mouth. Extensive observations of suspended load were made in the studies of Humphreys and Abbot near the middle of the Nineteenth Century, and the conclusions they reached were at variance with current opinion. These results led to a violent controversy with the late James B. Eads, F. Am. Soc. C. E., who about 1875 proposed to deepen the river mouths by jetties, and this discussion created considerable interest in solids load phenomena. Upon the formation of the Mississippi River Commission in 1879, extensive silt measurements were begun on the Mississippi and its principal tributaries, but were continued only two or three years. Except for the excellent summary of the studies of engineers all over the world published by Dr. E. H. Hooker in 1896,[9] little progress was made in this country on this problem until the work of G. K. Gilbert about 1914.[10] More recently, valuable work on the filling of reservoirs has been done by T. U. Taylor,[11] M. Am. Soc. C. E. A comprehensive description of the silt problem of the Lower Colorado was published by the late Carl Ewald Grunsky, Past-President, Am. Soc. C. E.,[12] in 1929. Another excellent report[13] on the Colorado River is that by the late Samuel Fortier, M. Am. Soc. C. E., and by H. F. Blaney, Assoc. M. Am. Soc. C. E.

---

[8] Prof., Hydr. Eng., Univ. of Iowa, Iowa City, Iowa.

The last few years, however, have seen an active interest in this subject in this country due largely to the return of the Freeman Scholars from Europe, where active work has been going on for many years, and to the importance which the problem has assumed in connection with the control of the Mississippi, Missouri, and Colorado Rivers, and in a number of beach and harbor problems. The subject is now, or has recently been, under active study at the U. S. Waterways Experiment Station at Vicksburg, Miss., the National Hydraulic Laboratory, the Bureau of Reclamation Laboratory, and at the laboratories of the Universities of California, Iowa, Minnesota, and the Massachusetts Institute of Technology. The result of this activity has been a considerable increase of knowledge in the science of transportation and control of the solids load.

Because of the great range of conditions, the solids load problems of the United States have had many aspects. The principal ones were the silting of reservoirs and the control of rivers, generally in fine material, for navigation improvement. The problems in other countries have also depended on local conditions. Formerly, the studies in Europe dealt principally with the control of rivers for navigation, and were concerned with bed-load movement, generally of relatively coarse material. More recently there has been considerable interest in the bed-load movement of finer material, as an outgrowth of efforts to represent the relatively coarse river bed material by finer material in model tests. The control of mountain torrents has also assumed considerable importance in recent years, and excellent studies are now (1935) being made of the suspended load problem.

Another large field for these studies has been the irrigation systems of India. There the investigations have been confined almost entirely to designing stable channel sections and the elimination of silt from canal intakes. The first of these was the classical paper by R. G. Kennedy,[14] published in 1895. This was followed by papers by Messrs. Lindley, Woods, Bottomley, and Griffith and, finally, the paper by Gerald Lacey.[15] The latter paper has stirred considerable interest in the subject and thorough research is in progress in several of the Provinces to determine the various factors controlling stable channel shapes.

In recent years, the silt problem of the Nile has been thoroughly studied in its relation to the silting of the irrigation ditches leading from it, but little has been published regarding the results. In the last few years considerable attention has been given to the silt in the rivers of China. In that country the problem is probably more vital than in any other. The floods of the rivers of North China are largely due to the tremendous loads of sediment brought down from their loess-covered drainage areas. The famous floods and channel changes of the Yellow River[16] are due to this cause. The silt concentrations in these rivers sometimes attain surprising values. S. Eliassen, Assoc. M. Am. Soc. C. E.,[17] reports that on the Ching River, "silt contents of 48% by weight were observed, and at one time 51%. The silt content often went above 30% and would stay above 30% for several days." He also states that in the 1933 flood the Yellow River at Sanchow Honan carried 39% by weight. O. J. Todd, M. Am. Soc. C. E., has reported 23.09% by weight on the Fen River,[18] and a maximum of 38% by weight has been reported in the Yung Ting River.[19] The only records in the United States comparable with these, as far as the writer knows, are those on the San Juan River, a tributary of the Colorado. A maximum of 40.8% by weight has been reported for this river by Howard and Love.[20]

It may seem queer that so little progress toward the development of a definite science should be made in a subject to which so much study has been given, but when one reflects on how many factors are involved, it is not surprising. The material transported by any section of a stream is the result of the interaction of two groups of factors. In the first group are those which influence the quantity and quality of the load brought down to that section of the stream. In the second group are factors which influence the capacity of the stream to transport load. A tentative list of these factors is as follows (these are not all independent and, in some cases, their effect is not definitely known):

Group 1.—Solids Brought Down to the Stream.—

(*a*) Quality: Size; specific gravity; shape; and dispersion.
(*b*) Quantity: Geology of water-shed; magnitude and distribution of rainfall; vegetal cover; cultivation and grazing; and erosion.

Group 2.—Capacity of Stream to Transport Solids.—

(*a*) Shape of Stream Prism: Depth; width; form; and alignment.
(*b*) Hydraulic Properties of the Stream: Slope; roughness, hydraulic radius; velocity; velocity distribution; turbulence; tractive force; temperature; and uniformity of flow.

Factors in Group 1 are subject to so many variations, not only between streams, but also at a given point of one stream, that analysis of any case in a quantitative way is impracticable. They resemble closely the factors controlling stream run-off, and, as in the case of run-off, about the only way they can be treated quantitatively is to observe them over a long period and record the results. Like records of stream run-off, solids load records are very valuable. In gathering so large a number of records from the scattered sources, Mr. Stevens has performed a valuable service. Too often a decision as to the construction of a project must be made before it is possible to collect sufficient data on the load of that stream, and recourse must be had to comparisons with loads observed on other streams. For this purpose, Mr. Stevens' data will be found to be invaluable. The present situation in regard to the solids load is much the same as that which existed in the case of stream run-off in the Nineties. In the future engineers may expect more solids load records to be collected until data will be available on all the large streams in the United States.

Although the prospect of a quantitative determination of the load brought down, derived from the various factors involved, does not seem practical, the study of the other phase, the capacity of a stream to transport material of a given quality, is making considerable progress. The relations between a number of the factors involved from the science of hydraulics is already known and the remaining ones are being subjected to close study. It is possible to study many of the these relations in the laboratory where the conditions can be controlled and the effect of varying only one factor at a time observed.

In general, the solids load is transported both in suspension and by rolling along the bottom as bed-load. The intermediate stage of saltation is usually unimportant. Apparently, the laws governing these two forms of transportation are different. The most recent work on the science of bed-load movement has been along the line of the relation between load and tractive force, and a solution of this problem seems nearer than that of the suspended load. Considerable study is also being given to the determination of laws of the transportation of solids in suspension. For many years this has been a matter of controversy among engineers. In Hooker's[9] thorough review of the pertinent literature first published about 1896, he set forth the two principal theories: (1) That the solid material is held in suspension by the difference in velocities between adjacent filaments of water; and (2) that it is held in suspension by the upward movement of currents or eddies in the flowing water. Both these theories are still widely held to-day and progress will be accelerated when the false one is abandoned. The first of these theories was developed by Dupuit[n] who rotated a glass of water containing sand grains and from the action of the sand concluded that the particles tended to move toward the fastest moving water, and, therefore, were lifted toward the surface in a stream.

The writer has never been able to accept this theory for several reasons One is that according to it there could be no material in suspension above the point of maximum velocity in a stream, since above this point the velocity gradient would usually be downward and, therefore, there would be no force lifting the particles against the force of gravity. It is well known, however, that sediment does occur in suspension above the point of maximum velocity. Furthermore, if Dupuit's theory were valid, in a dredge pipe through which water and sand were flowing at high velocity, because of the high velocity gradients which would occur toward the center of the pipe, there would be great forces tending to move the material toward the center of the pipe and hold it there. This would leave the remainder of the pipe filled with practically clear water. No such action has been observed. A third reason is that in large, deep channels, the differences in velocity at the two sides of a small particle of silt are so minute that it seems unreasonable to believe they could generate enough force to hold the particle up against the attraction of gravity.

In order to inquire more fully into the claims of the Dupuit theory, the writer has recently experimented with sand in a revolving glass vessel, as Dupuit did, and finds as much evidence to support the turbulence theory as that of Dupuit. As a result of these experiments and the three reasons mentioned previously the writer is convinced of the fallacy of the Dupuit explanation of the suspension of solids in flowing water and confirmed in the belief that solids are carried in flowing water by the upward currents and eddies.

It is not difficult, however, to account for the persistence of the Dupuit theory through many years, in spite of the unanswerable objections which have been raised against it. Although the velocity gradient does not produce the forces causing the solid particles in suspension to move against the force of gravity, a high velocity gradient usually indicates high turbulence, and, therefore, a region of high suspending ability. The velocity gradient and suspending forces, therefore, are related but not, as Dupuit supposed, in a cause and effect relation.

---

[n] "Etudes," par. J. Dupuit, p. 220.

The most recent studies in the suspended load problem from the theoretical standpoint in this country have been along the line of relating suspended material and turbulence. The work of Professors O'Brien and Leighly has already been mentioned in the paper. Since the paper was written, an additional paper by Professor Leighly,[22] and one by Professor von Kármán[23] have added much to an understanding of the problem.

Related to the problem of turbulence and suspended load transportation is a striking phenomenon which one often sees on the surface of a canal or stream of very muddy water. This is a streak of practically clear water, surrounded by very turbid water. As this phenomenon throws some light on forces keeping particles in suspension it was closely observed by the writer. The cause of this phenomenon seems to be, as follows: When the water at the surface of a flowing stream is undisturbed for a short period the silt settles down, leaving at the surface a thin unnoticed layer of desilted water. Throughout the stream, however, there are eddy currents rising from within the water prism to the surface. In moving through the mass of water, they encounter comparatively little resistance on their upward course, the action of the force of gravity being balanced by a downward movement of an equal quantity of water in another part of the stream. When they reach the surface and attempt to rise higher, their motion is not balanced by an equivalent downward motion and their upward momentum, which is relatively small, is quickly overcome by the force of gravity. These upward currents then spread out in an umbrella shape in all directions near the surface of the stream. If two of these upward eddies come up on opposite sides of any area where there is a slight layer of clear water, as previously described, the eddies spreading out on the surface squeeze the clear water layer between them together, until it forms a narrow streak of clear water which has sufficient depth to be apparent to any observer.

In addition to being a noticeable phenomenon, this action probably is an important factor in the mechanics of the transportation of solids in suspension, as it seems to explain the reason why the maximum velocity in a stream occurs below the surface, which must be taken into account in any complete and rational treatment of the suspension of silt in streams. The mass of water in these eddies in passing up from the bottom moves through the main body of the water and retards its longitudinal motion somewhat, because having originated at the bottom, the longitudinal motion of the eddy is slower than the average of the mass. The greatest effect, however, is at the surface, where the eddies spread out and join together to form the top layer, with a lower longitudual velocity than the water immediately below. The eddies which cause the visible clear-water streaks previously mentioned are of considerable magnitude, but smaller eddies no doubt similarly contribute to the upper, slow-moving layer. There seems to be no reason why the limitation to motion imposed by the surface of the stream should not have a similar effect on the intimate internal motion which makes up the turbulences in the flowing water. As the observation on the silt transported in a stream led the writer to a better understanding of an idea of the internal mechanics of the flow of water in an open channel, it seems probable that knowledge of the internal mechanics of flowing water and its turbulence may perhaps be reached more efficiently by the study of the transportation of solids in suspension than by observations on clear water flowing in channels.

FRANK E. BONNER,[24] M. AM. SOC. C. E. (by letter).—Contributions to technical literature on the important subject of silt movement and control are increasing in desirable degree. The comprehensive paper by Mr. Stevens provides a notable addition, and the author deserves particular commendation for the large amount of effort obviously expended in the correlation of the statistical data presented by Table 6. The inclusion of the large number of determinations made by the Corps of Engineers, U. S. Army, during the past few years throughout the Mississippi Basin, bridges a gap existing in previous tabulations. It is evident, however, that a number of the recorded observations cover too short a period for the determination of dependable normals, and some caution will have to be exercised in the use of the data for such purposes. The same is true in regard to part of the voluminous data abstracted from *Water Supply Paper 274* of the U. S. Geological Survey. For example, Item No. 2, Table 6, is based on measurements made at Palisade, Colo., on 160 days of an elapsed period of 399 days in 1905 and 1906. The silt load value is given as 0.49 part per thousand. However, analysis of the same data reported in *Water Supply Paper 617* gives 4 000 000 acre-ft and 1 758 700 tons (950 acre-ft at 85 lb) as the estimated annual water discharge and silt load, respectively. These data give a silt load value of 0.323 part per thousand which is less than the tabular value by about 34 per cent. Similar discrepancy between different interpretations of results is illustrated by Item No. 3, Table 6, and others. It is thus apparent that, for detailed uses, reference to the original sources of data may be desirable.

The paper refers to the reservoir silting problem with considerable emphasis on the hazards of ultimate depletion. The writer prefers to view this problem with less alarm concerning the possible misfortunes of the remote future. Somehow, these threatened disasters due to "impending exhaustion" of different elements of natural resources never seem to materialize with the serious results anticipated. Imminent shortages automatically set in motion the ingenuity of mankind toward the provision of substitutes which generally serve better than the materials displaced. Consider the lumber situation for example: Decreasing per capita consumption due to rapid increase in the use of wood substitutes has relieved the pressure on the timber resources of the United States. Experts concede that "the threat of a timber famine which loomed so large some 25 years ago has somewhat worn off."[25] Likewise, in the case of the water power resources; several decades ago extensive public concern arose over their adequacy to meet future requirements. To-day, water power development is in the discard, due to the amazing increase in the efficiency of steam-electric generation and the widespread production of cheap fuels. Past bugaboos relative to impending scarcity of fuels, farm lands, fertilizers, and other resources have gone through the same cycles. Present fashion tends toward "saving the soil from erosion" and this movement will probably have to run its course.

---

[24] Cons. Engr., Piedmont, Calif.

The accumulation of silt, of course, is one of the elements to be considered in the case of every proposed reservoir. Rapid depletion of capacity may affect the economic plan of the project and, perhaps, even the design of the dam. Fortunately, however, the problem is not serious in many cases. Rapid depletion of capacity is rather well restricted to the reservoirs on the silt-laden streams of the arid Southwest and to those with capacities disproportionately small in relation to the area of their tributary water-sheds.

Elephant Butte and Boulder are frequently cited to illustrate the transitory character of reservoirs. Silt conditions at both structures were fully recognized by the builders. It is probable that no streams in the United States have been studied in regard to silt transportation more thoroughly than the Rio Grande and the Colorado River. The excessive débris-producing capacity of these water-sheds will be continuous. Herman Stabler, M. Am. Soc. C. E., has showed[26] the impracticability of arresting erosion in these arid regions by so-called "water-shed protection" methods.

Actual accumulations of silt in Elephant Butte Reservoir, since its completion in 1916, correspond closely with the forecasts based on studies made prior to its construction. Unless serious errors have been made in the economic programs of these projects, it is reasonable to assume that the capital outlays will be amortized long before sedimentation of the reservoirs seriously impairs their usefulness. When that time eventually comes, any desirable restoration of capacity will be a problem for the engineer of that distant day. If engineers attempt to provide a solution now, it would propably be found entirely wrong long before the time arrived for its application.

On the basis of present conditions, ultimate construction of new storage would doubtless be considered the proper remedy; but under the unpredictable conditions of the dim future dredging, sluicing, or some other means may be found more economic. Moreover, considering the amazing march of science in the recent past, it is conceivable that water storage requirements 50 yr or 100 yr hence may be on an entirely different basis than the present. History teaches the futility of trying to peer very far into the future.

Various estimates have been made relative to the average rate of surface leveling in the United States based on silt movement. Mr. Stevens cites an estimate published twenty-five years ago by the U. S. Geological Survey giving the annual total of suspended matter at approximately 500 000 000 tons. The accumulation of more recent data supports the writer's estimate of about 933 000 000 tons.[27] The frequently quoted figure of 3 000 000 000 tons, attributed to the Federal Soil Erosion Service, is clearly excessive.

Morrough P. O'Brien,[28] Assoc. M. Am. Soc. C. E. (by letter).—The compilation on the silting of reservoirs which is contained in this paper shows clearly the economic importance of the silt problem and the necessity for a continuation of investigations in this field. A paper by Dr. Fritz Orth[29] dealing with the same subject and published almost simultaneously contains much additional information, including the data given in Table 10. All the numerical values have been converted to the same units as those used by the author.

The author mentions several estimates of the percentage of the total silt transportation which moves as bed-load. Any such estimate must be made on the basis of some arbitrary quantitative definition of what is meant by bed-load. As the tractive force moving the material increases, the region of bed transportation gradually expands until the concentration at or near the surface becomes appreciable and a condition of suspension is said to exist. Measurements show, and the theory of turbulent flow indicates, that the concentration of material should increase downward, the rate of increase becoming greater for larger materials. When materials in suspension are being transported over a mobile bed containing the same material, it is doubtful whether the bed has a well-defined surface along which material could be said to move as bed-load. In the laboratory, bed-load is defined as that material caught in a properly designed trap, whereas in studies of sedimentation in reservoirs or lakes it is the difference between the volume of material deposited and that accounted for by measurements of suspended sediment and discharge. Whatever the definition may be, the percentage of bed-load rises abruptly to 100 as movement starts and then decreases as material is thrown far enough into the stream to be classed as suspended material. Therefore, it is different for every stage of the river.

Some progress has been made in the application of the theory of turbulent flow to the distribution of suspended sediment[30] and the greatest obstacle at present is the lack of precise data. W. Schmidt[31] has developed the basic equation and some data are available for checking it, but much more will be needed before its validity can be fully established. The basic data needed are: Measurements of the vertical distributions of velocity and sediment; and the

fall-velocity of the material in suspension. Useful supplementary data are: The size of the bed material; the hydraulic radius or depth; and the energy slope. This need is mentioned in the hope that engineers taking sediment samples will also obtain the other data mentioned.

In Table 10 the variation in silt deposited per thousand parts of water supply, by volume, is from 0.028 to 16.3. Interesting as these data are, they do not provide a means of predicting the life of a proposed reservoir and this is the principal problem involved. Most of the factors causing this wide variation are mentioned by the author. Further progress in this field appears to require a breaking down of the problem into two phases, of which one is the volume of sediment transported by the stream and the other, the characteristics of reservoirs as a silt trap. Laboratory and field studies can contribute much valuable information on these points, but any prediction of the rate at which sediment will be transported to a reservoir is necessarily subject to all the uncertainty involved in forecasting stream flow.

On the assumption that a given project will continue to need the volume of effective storage originally provided for it, the monetary damage caused by silting should not be computed from the cost of the original reservoir but from the cost of the necessary additions. As the sites which are less expensive per unit of storage are developed first, silting involves an increasing rate of damage as it proceeds and it may ultimately be impossible to provide sufficient storage capacity at any cost. At present, construction of additional reservoirs appears to be the practical solution, but the time may come when by-pass channels and other silt-controlling works, costing perhaps more than the dam itself, will be found to be economically justified. Such structures are now used successfully at diversion dams, and it seems possible that conditions at some storage dams might warrant the construction of works for diverting a portion of the silt.

HARRY F. BLANEY,[33] M. AM. SOC. C. E. (by letter).—The author calls attention to facts which have often been overlooked in the past. The paper is a valuable contribution to the literature on the subject of silt. Since the writer is more familiar with conditions along the Lower Colorado River and the Middle Rio Grande, this discussion will be confined to the areas served by these streams through the reaches mentioned.

As indicated by Mr. Stevens, silt is a menace to irrigated agriculture in some sections. This problem is one of the most serious confronting the people of New Mexico to-day, especially in the Rio Grande Valley. This valley supports about one-third of the people of the State, as well as a large population in Texas. The silt problem of the Middle Rio Grande may be divided into three phases: (*a*) The silting of the river channel above Elephant Butte Reservoir; (*b*) the deposition of silt in the Elephant Butte Reservoir; and (*c*) the accumulation of coarser silt in the main stream channel below the Elephant Butte Dam, due to lack of seasonal flood flushing. The Federal Governments of the United States and Mexico have started a project to rectify the conditions below the dam. Recently, the State Planning Board of New Mexico has recommended that a relief project be undertaken to control erosion on the Rio Puerco, which is the principal source of silt in the Upper Rio Grande water-shed, and reports[33] that:

---

[33] Irrig. Engr., Bureau of Agri. Eng., U. S. Dept. of Agriculture, Los Angeles, Calif.

> "The Rio Grande Valley is in great danger of destruction as a habitation for man, due to the rapid erosion of its tributaries and silting of the river itself. In approximately 50 years the great Elephant Butte Dam and irrigation works connected with it will lose their usefulness, due to the silting up of the reservoir and the destruction of its storage capacity."

It is estimated in this report that silt endangers an investment of $100 000 000 in land and improvements. The river above the Elephant Butte Dam for a distance of 150 miles has such a moderate fall that in many places a large quantity of silt is deposited. This building up of the river channel is increasing flood hazards and water-logging the bordering lands. Surveys made in 1934 show a rise of the river channel at La Joya (just below the mouth of the Rio Puerco) of 7 ft since 1918; at Albuquerque, 2 to 4 ft; and at Alameda, 1 to 3 ft. The most important stream that enters the Rio Grande above Elephant Butte Reservoir is the Rio Puerco, and its control would go a long way toward solving the silt problem.

As indicated by the author, the Boulder Reservoir will not completely solve the silt problem on the Lower Colorado River. On March 1, 1935, about 110 000 acre-ft of water had accumulated in Boulder Reservoir, and the water leaving it was clear. However, an additional silt load will undoubtedly be picked up by the river below the dam for some time to come. If the experience on the Rio Grande below Elephant Butte Dam is repeated on the Colorado River, the clear water released from either Boulder Reservoir or from Parker Reservoir will pick up a load of silt and scour the bed, progressively lessening in depth but extending in distance. With an average discharge of 15 000 to 20 000 cu ft per sec, the bed of the river will probably be washed in time so that most of the fine silts will be removed and only the bed sands left to line the channel. Occasional floods entering the river below the Boulder Dam or the Parker Dam will carry large quantities of silt and will cause a temporary increase of suspended silt in the river at the Imperial Valley Diversion.

The character of the silt will be changed materially, since it will be a mixture of silt picked up from the bed of the river. This will consist of silts from different tributaries of the river, no one of which will predominate.

There is a difference of opinion among engineers as to how many years it will take the regulated river to clean its channel of the finer silts and cease to carry any appreciable quantity of material in suspension.

With the river unregulated, a low percentage of suspended silt usually occurs in the early summer at the peak of the annual flood resulting from the melting of the snows in the upper water-sheds, while the river water generally carries the highest percentages of silt in the late summer months or fall when erratic floods are caused by rains in areas drained by its lower tributaries.

---

[33] "Silt Control on the Rio Puerco," by S. R. DeBoer, Mimeographed Rept., New Mexico State Planning Board, November, 1934.

The writer believes that the low percentage of silt carried in suspension by the river in past years is a good index of what may be expected immediately after Boulder Reservoir becomes effective in desilting the water. The annual quantity of silt carried in suspension in the river will be reduced by at least one-half at the Imperial Valley Intake, and for the most part, the large quantities of objectionable fine silt which have been present in the water during the peak of the irrigation season will be eliminated.

When the new Imperial Diversion dam and heading are completed about five miles above Laguna, a portion of the present main canal serving the Yuma Project will probably be abandoned, and its water brought through the upper end of the All-American Canal. Laguna Dam will remain, to serve as a drop structure in the river, controlling recession of grade below Imperial Dam. It has been estimated that it will take from three to five years to complete this project. Meanwhile, Imperial Valley will receive water through the present system, and silt conditions will be about the same as heretofore.

The effect of silt on the cost of operation and maintenance of the irrigation system in Imperial Valley has been a serious one. The use of silty water for irrigation as it comes from the river means the handling of an enormous quantity of silt, which, of necessity, must be deposited in the various canals of the system, or on the land itself. In some sections it is necessary to keep dredgers continually at work in order to maintain the canals and laterals in condition to carry the required quantity of water. The disposal of this silt dredged from the canals is also fast becoming a perplexing problem. The banks of the canals are constantly being raised and widened. The Imperial District spends approximately \$500 000 per yr for silt disposal. In addition, there is the cost of cleaning farm ditches and re-leveling of land because of silting. A survey by the U. S. Bureau of Agricultural Engineering in 1933 indicated that the total cost of cleaning ditches and re-leveling land as a result of silt deposits in Imperial Valley ranged from 55 cents to \$4.63 per acre per yr and averaged \$1.80. This is in fair harmony with the usual estimate of \$2.00. Applying the latter figure to the 400 000 acres under irrigation in the Valley, the cost would reach \$800 000 per yr. Adding to this the amount spent by the Imperial Irrigation District gives a total annual cost of silt disposal of more than \$1 250 000.

Several different plans for the exclusion of silt from the All-American Canal, both bed and suspended load, have been considered. Research investigations being conducted by the U. S. Bureau of Reclamation and the Bureau of Agricultural Engineering are expected to furnish the fundamental data for the preparation of the final designs for desilting works at the new Imperial Dam. The Bureau of Reclamation has been successful in eliminating about 50% of the suspended silt and most of the bed silt in the desilting operations at Laguna Dam.[84] The writer feels confident that when the new

---

[84] "Silt in the Colorado River and Its Relation to Irrigation," by the late Samuel Fortier, M. Am. Soc. C. E., and Harry F. Blaney, Assoc. M. Am. Soc. C. E., *Technical Bulletin 67*, U. S. Dept. of Agriculture, 1928, p. 58.

Imperial Heading is finally built it may be expected to eliminate practically all the bed silt and at least 50% of the suspended silt carried by the river water. With the regulated river carrying 50% of its former quantity of suspended silt only 25% of the former suspended load would enter the irrigation system. However, it will be advisable to retain some silt in the water so as to prevent the growth of moss. Under these conditions the annual expenses to the individual farmer of cleaning farm ditches and re-leveling land, and to the Imperial Irrigation District for silt disposal, would be reduced considerably.

W. W. WAGGONER,[35] M. AM. SOC. C. E. (by letter).—In an exhaustive and comprehensive manner Mr. Stevens has presented "the silt problem" for discussion. His description of the silting presents a dark and important picture. The tabulation of the quantities of silt transported by the various rivers is indeed startling. It shows how much greater the mud flow is from the sedimentary and fragmentary formations than from the crystalline rocks.

The answer to the question of preventing the silting of a reservoir is to build another one above it, to impound the silt, and also to encourage the deposition of silt above the reservoir as in the case of Lake McMillan which the author mentions. It would be interesting and constructive to the discussion of the paper if a detailed description of the silt impounded at Lake McMillan could be given.

The gold mines of California are drained by the Yuba River, a tributary of the Sacramento River. This area has been the scene of the most important operations in hydraulic mining. Due to his long contact with the gold-mining industry, the writer has made a detailed study of the débris problem in its various phases and desires to record the débris deposit in the Yuba River, and its relation to the subject under discussion.

Denudation is more than the eroding of the mountains, and the filling of the rivers with sand, or the forming of deltas at the river's mouth. It is one of the grandest features of the Creator's plan for maintaining the fertility of the soil for the benefit of mankind throughout the ages. Consider the nature of the soil: Professor E. W. Hilgard[36] has stated that the soil is composed of 3 to 5% of organic matter, and 97 to 95% of inorganic matter from which the plants obtain the nine mineral elements that enter into their growth, namely, phosphorus, potassium, calcium, magnesium, sodium, iron, silicon, chlorin, and sulfur. These elements combine to form the common minerals such as feldspar, mica, and hornblende, which compose the crystalline rocks.

It may be stated that the valleys are the granaries from which the people obtain the major portion of their food, and that the mountains are the storehouses from which the depleted soils receive a new supply of fertilizer. The action of the elements is to break up the cementing power that holds the minerals in a solid mass, and to form individual grains that compose the fine, inorganic part of the soil. These, in turn, are also oxidized, and the elements are slowly dissolved, and carried into the soil for plant food. It is remarkable how a thin soil, with an adequate precipitation can produce a great forest growth, due to the abundance of plant food.

---

[35] Hydr. and Min. Engr., Nevada City, Calif.

[36] "Geochemistry," by E. W. Hilgard, *Bulletin 491*, U. S. Geological Survey.

For example, consider Central California, on the western slope of the Sierras, with its great forests and its abundance of precipitation. During the dry seasons the erosion is negligible, but during the wet, or flood, seasons it becomes of great volume. The storms beat against the mountain slopes where they dissolve the plant food and carry it away with the particles of sand into the ravines and creeks. These waters concentrate into streams which debouch into the valley. By so doing, great canyons are formed and mountains leveled. With the heavy grades, and high velocities, the streams are capable of carrying all the silt brought to them. When the valley has reached the flatter grades, sand and gravel are deposited upon their beds. The finer material is carried onward. During floods the water spreads over the valley; some of it soaks into the ground where, at least, a part of the dissolved plant food is left behind to act as a fertilizer.

With the occupation of the valley these flooded lands are very attractive for farming. Levees are constructed to protect these lands from the floods and to get rid of the so-called nuisance. The finer sands, together with the dissolved matter, of necessity are transported to the bays and the ocean.

As an illustration of the fertility of such land may be cited the case of a farm with 270 acres in wheat, 10 acres of which were measured and shown to produce 50 470 lb. In 1858, the wheat from this tract was so rich in gluten that it was in great demand in the markets of New York, N. Y., and Liverpool, England. To-day, 1 000 lb per acre is an average yield, but the wheat is so poor in gluten that it has to be mixed with other wheat from new lands to make a marketable flour, due to the depletion of new plant food.

Consider next the history of a great débris deposit upon the Yuba River, which is comparable to that at Lake McMillan. After a long period of industrial depression in the United States, gold was discovered in far-away, unknown California, on January 24, 1848. This discovery electrified the world. A man could go to California, accumulate a fortune by gathering gold from its sands, and then return home to live in peace and comfort for the remainder of his days!

Never was there such an army of active, energetic, educated, and resourceful men as gathered in California. While many followed their original plan, most of them remained to found a State. They had to be housed and fed. This led to the opening of farms, and the setting out of orchards. All the best lands were brought into cultivation. Ten years after the discovery of gold there was a greater acreage of farms on the Yuba drainage area than there is to-day. These industries needed lumber to carry on their operations and for the towns that grew up not only in the mountains but in the valley as well. In 1859, there were ninety-nine saw-mills in the three counties covering the Yuba drainage area. The long, dry seasons were ideal for lumbering.

It can well be imagined how the ground was plowed up by the ox teams that were used for snaking the logs to the mills. This continued for about thirty years, or until the wonderful forests (which would be hard to find elsewhere) were exhausted.

In November, 1861, a cycle of wet winters began, which continued for twenty years, and produced the worst floods in the later history of the State. During December, 1861, and January, 1862, four great cyclonic disturbances occurred that enveloped the entire Pacific Coast, and produced floods, from the Columbia River to and including Los Angeles, Calif. In the Sierras it was commonly called "The Deluge." Upon the middle belt of the Sierras during these months 75 in. of rain fell, and near the summit 42 in. of rain and 50 ft of snow fell; 5 and 6 in. per day fell during a 4-day period. A seasonal total of 109 in. occurred in the gold belt.

Combining the stories of the historians of that period the water flowed into the valley at a greater rate than could be discharged through the Carquinez Straits, and the Golden Gate. From the foothills of Mt. Shasta to those leading up to the Tehon Pass the great California Valley was a vast lake not unlike the shape and size of Lake Michigan. The tides ceased to act, and a stream of thick, muddy water flowed through the Golden Gate, which discolored the ocean for a distance of 40 miles from the land. The bays became fresh, killing the oysters which were planted near Oakland.

The Yuba River discharged its quota coming from its various tributaries surcharged with mud and sand gathered from the mines, fields, and forests. The Lower Yuba River bottoms was a narrow valley, 1 mile to 3 miles wide, carved in the peneplain of the valley. The mud and sand buried the farms and orchards 15 ft deep; with the succeeding years came more floods and with them the deposit increased in depth until it was raised about 10 ft above the general valley plain. Levees were constructed to confine the deposit. One of the results that occurred as soon as the deposit reached the level of the valley floor was to raise the water-table on the adjacent lands. It was brought out in the litigation which followed that they were known as "redlands" and were poor even for grazing. After the raising of the water-table they were used for general farming.

In the early days the gold was recovered from the gravel by washing in sluice-boxes, the gravel being moved principally by picks and shovels. In 1870, mechanical equipment was invented by which means a considerable volume of water could be used under high heads, and a large volume of gravel could then be moved at a reasonable cost. These giant machines are now used in the construction of hydraulic-fill dams and similar structures. This equipment led to the consolidation of small holdings and the formation of large companies financed in San Francisco, New York, and London. Reservoirs, the highest in the United States, were built, and long lines of canals were constructed to the mines. These structures were completed about 1876.

At the same time the agitation against the débris flow that began after the floods of 1862 and (were charged against the mines) took the form of litigation which culminated in the injunction that closed the mines in 1884. During the litigation, the State Engineering Department of California was created. Elaborate surveys of the navigable rivers and the Yuba River were made. In 1894, the Army engineers made a series of borings to determine the depth of the deposit. These borings were supplemented by those of the gold dredgers.

Combining the various surveys it was found that the deposit which was 20 miles long, had a maximum width of 3 miles, covering 16 000 acres and containing 600 000 000 cu yd. It was 20 ft deep at the river's mouth, 35 ft deep at the edge of the foothills, and 80 ft deep 5 miles higher up the Yuba River. The grade of the original bed was 5 ft per mile. After the fill was made, the grade per mile was 2½ ft at the mouth, 10 ft at the middle zone, and 20 ft on the upper reaches.

The deposit soon became covered with a dense growth of willows. It remained intact with a few, low-water channels coursing through it. About 25 yr ago the Government enlarged the main low-water channel until now (1935) it will carry a moderately large flood. Much of the adjacent land that was supposed to be destroyed forever was cleared and planted to pears, the uncleared land being held at more than $250 per acre.

In making the deposit the law of transporting material is probably the same as that which obtains in the sluices of the hydraulic mines. It is known that with water flowing 10 to 12 in. deep the transporting capacity varies directly as the slope. Furthermore, with water flowing 2 ft deep, more material will be carried per cubic foot per second than with water flowing 10 in. deep. Mathematically, the transporting capacity of force, F, varies as V^3.

It is interesting to record that fields which were denuded of their soil are now covered with second growth pine and brush. One variety of brush known as "sweet birch" is especially valuable as a cattle food. One enthusiastic cattle man claimed that it was nearly as good as alfalfa, and made it a practice to gather and scatter the seed over his range; while another farmer claimed that a good soil could be formed by it in 25 yr.

The lesson of the débris deposit on the Yuba River is of far-reaching application. By spreading the water over a wide area by low barriers, and by encouraging brush growth, the silt will be deposited and can be raised to any height. The material thus impounded will be prevented from moving down stream, filling reservoirs, or from entering the navigable rivers where it would have to be dredged at a cost of 6 or 7 cents per cu yd. Below the barriers the stream will then be able to scour its bed and increase its capacity. The cost of such impounding will be less than 1 cent per cu yd. It is conservation in the highest degree.

PHILIP R. R. BISSCHOP,[37] ASSOC. M. AM. SOC. C. E. (by letter).—In South Africa the silt problem is no less severe than that encountered in the south-western part of the United States. Of late years particularly, the rapid rate of silting recorded in many of the irrigation reservoirs has caused considerable concern. In a number of cases the very existence of productive centers of population is threatened, and for what period of time it will be possible to preserve the present water supply is a moot point. Indeed, it is the definite policy of the present Government to limit the extensive further program of irrigation development to those rivers that are least subject to silt encroachment.

---

[37] Cons. Irrig. Engr., African Consolidated Investment Corporation, Johannesburg, Union of South Africa.

Typical of some of the conditions encountered in this country is the case of the Sundays River, in the Cape Province. Rising at elevations of 6 000 to 7 000 ft, this river drains about 6 000 sq miles on the south escarpment of the Sneeuwberg Range which divides the Great Karroo Plateau of 4 000 to 5 000 ft elevation from the Small Karroo Plateau of 1 500 to 2 000 ft. In the foothills of this inclined plane, on the main branch of the river, is situated the Van Ryneveld's Pass Reservoir with a catchment of 1 500 sq miles. At the southern edge of the Small Karroo Plateau, where the river starts breaking through the coastal ranges, is situated Lake Mentz Reservoir with a catchment area of 4 500 sq miles.

The entire drainage area can be divided roughly into the "Mountain" Section and the "Flats" Section, the first-named reservoir taking on part of the mountain topography whereas the second takes care of the remainder of the mountain area and all of the "Flats" Section.

The average annual rainfall varies from 14 to 18 in. in the mountains to from 10 to 14 in. in the flats. Approximately 80% of this rain is concentrated in the summer months, particularly February and March. Consequently, the river flows are essentially ephemeral in character and are liable to exceedingly high flood peaks in very short periods of time, falling again with only slightly less suddenness.

Previous to the building of the reservoirs, intermittent irrigation was practised extensively, by what is known as "flood furrow irrigation"; that is, individual small systems diverting water into fairly large canals in order to obtain a maximum of water in a minimum of time whenever available. Such irrigation was necessarily of an exceedingly up-and-down character, incapable of sustaining much more than "snatch" crops and occasional cuttings of alfalfa. With the completion of the reservoirs, land development and settlement occurred along lines quite similar to those experienced in the United States. To-day, both reservoirs sustain intensively developed irrigated areas, subdivided in small holdings on which a struggling population is obtaining a living from citrus, deciduous fruits, alfalfa, and cereal crops.

Below the reservoirs, therefore, there is a cropped area totally dependent on conserved water, and above them, a pastoral area subject to severe droughts and high floods. In the past, the latter area has been subjected to extensive over-grazing and although to-day the more progressive farmers are fully alive to the decreasing grazing capacity of their farms and are actively endeavoring to rehabilitate their veldt, the damage already done by soil erosion is such that it has become a national problem against which the incumbent Government has organized an intensive campaign of research, subsidization of anti-erosion work and rehabilitation of the original vegetation. The benefits of such work can necessarily only become apparent over a considerable period of time and cannot be other than partial in overcoming all erosion. In the meantime, the lower lying reservoirs are gathering the accumulated burden. For example, Lake Mentz, completed in 1922, has silted up to 42.3% of its original capacity (see Table 11), say, in twelve years of life, and Van Ryneveld's Pass is estimated to have lost 16.4% of its capacity between 1925 and July 1, 1933.

* Date of closure. † Based on actual survey ‡ Mean of Column (5). § Based on previous survey findings.

In the case of Lake Mentz, the raising of the dam has already begun and the levels of other reservoirs (such as Lake Arthur on a tributary of the adjoining Great Fish River) will have to be raised in the near future. Such periodic raising of the dam walls is necessarily limited, if not by physical features, certainly by financial considerations. Already, in a manner very parallel to that experienced in the United States, the administrators of many of the South African irrigation projects have found it impossible to meet their redemption and interest rates, and the Government, which financed the projects, has found it necessary and expedient to write off approximately $25 000 000—the entire capital loans and arrear interest payments of a large number of projects. In agreeing to these "write-offs," the Government stipulated an annual assessment of approximately $0.30 per acre for the special purpose of establishing in each project a reserve fund to cover the cost of periodical heightening of the dam walls. The amount of this assessment cannot possibly be expected to cover the increasing cost of preserving the water supply. What then is to become of the endangered projects? Where further reservoir sites are available, or where the existing reservoir sites are not as yet fully developed, the problem resolves itself to an extension of the already widely held viewpoint that irrigation development is essentially a national function and that, as such, the Government should not only finance and subsidize—either directly or indirectly—the original cost, but also that of preserving the supply.

Further supplies are not always available, however, and existing reservoir sites must ultimately become fully developed if they are not developed already. Furthermore, public opinion may not support the conception that it is the function of the Government to preserve a water supply for an unlimited period. There appears to be only one solution, namely, to recognize frankly that some irrigation projects are doomed to a definite span of life and will have to revert back to the original type and manner of flood irrigation, to prepare the irrigators against such time and contingency, and, in the meantime, to delay the end as long as possible by actively combating sheet and river erosion within each catchment area.

The detailed technical data pertaining to the deposition of silt in the Van Ryneveld's Pass Dam are:

Drainage area, in square miles	1 475
Mean (estimated) annual supply, in acre-feet	38 000
Original full supply capacity, is acre feet	64 200
Percentage of annual supply, $\left(\frac{64.2}{38.0} \times 100 = \right)$	169
Date of reservoir completion	1925
Elapsed time, in years, between completion of reservoir and last capacity survey	6
Water supply, in acre-feet, during the six-year period	134 600
Silt Deposited, in Acre-Feet:	
Total	5 244
Annual	874
Percentage of original capacity	7.4
Percentage of original capacity, by volume $\left(\frac{5\,244}{134\,600} \times 100 = \right)$	3.9

Since the date of the last capacity survey (February, 1931), a flood of 100 000 acre-ft passed through this reservoir, on January 1 and 2, 1932. By July 1, 1933, it was estimated that, in all, 10 500 acre-ft of silt had been deposited with a reduction in capacity of 16.4 per cent.

Lake Mentz is a non-overflow, gravity dam provided with five Stoney gates, 30 ft wide and 25 in. high. In March, 1928, a flood of 356 000 acre-ft entered the reservoir, of which 310 000 acre-ft passed through the gates. During the flood of January 1 and 2, 1932, furthermore, 421 000 acre-ft were by-passed through the gates. At Van Ryneveld's Pass, the dam is of the overflow, gravity section, type and has only been in action once when 46 000 acre-ft were spilled.

It will be noticed from Table 11 that the percentage, by volume, of silt retained at Lake Mentz is only 2.3 as against that of 3.9 at Van Ryneveld's Pass. This may be accounted for, possibly, by the lesser run-off and lesser erosion from the flatter and, at the same time, lower rainfall portion of the catchment area as against the higher run-off and greater erosion in the

Mountain Section. It may also be accounted for by the probability that a certain quantity of the suspended and bed-load is scoured out by the gates as against the skimming action of an overflow type of dam. The two reservoirs also provide an interesting illustration of the effect of the size of the mean annual run-off and the storage capacity on the life of the reservoir. Although Lake Mentz has a lower volume percentage of silt and a 50% larger storage capacity, the annual run-off from the larger catchment is such that its life, theoretically, is 30 yr as against 50 yr for Van Ryneveld's Pass.

Considerable work has been done in the United States in estimating the life of reservoirs by silt sampling. In this connection, the writer would like to recall the work and method of approach adopted by Mr. C. H. Warren, while he was Circle Engineer of the South African Irrigation Department. Silt samples were taken in bottles and analyzed both for specific gravity and silt percentage by weight, and a curve was obtained expressing the relationship. From samples taken from the bed of the Great Fish River, Mr. Warren obtained a weight of 52.8 lb per cu ft of dry silt, or 84.6% of the weight of 1 cu ft of water. A hundred cubic feet of water, containing 1% by weight of silt, therefore, will deposit $\frac{100}{84.6}$, or 1.18 cu ft of silt. As the silt percentage increases, so also will the weight per cubic foot of water laden with that silt increase. Therefore, he calculated a ratio, *R*, expressing the relationship between the percentage by volume and the percentage by weight for increasing loads of silt in the water (see Table 12).

TABLE 12.—RATIO OF PERCENTAGE BY VOLUME TO PERCENTAGE BY WEIGHT FOR INCREASING LOADS OF SILT

Specific gravity (1)	Weight of 1 cubic foot, in pounds (2)	Percentage of silt by weight (3)	Ratio, $R = \frac{\text{Percentage by volume}}{\text{Percentage by weight}}$ (4)	Percentage of silt by volume (5)	Specific gravity (1)	Weight of 1 cubic foot, in pounds (2)	Percentage of silt by weight (3)	Ratio, $R = \frac{\text{Percentage by volume}}{\text{Percentage by weight}}$ (4)	Percentage of silt by volume (5)
1.000	62.42	0.00	1.182	0.00	1.040	64.92	5.86	1.230	7.21
1.005	62.74	0.73	1.188	0.87	1.050	65.55	7.32	1.241	9.09
1.010	63.05	1.46	1.194	1.74	1.060	66.17	8.79	1.253	11.08
1.015	63.36	2.20	1.200	2.64	1.070	66.79	10.25	1.265	12.97
1.020	63.67	2.93	1.206	3.53	1.080	67.42	11.72	1.277	14.97
1.025	63.99	3.66	1.212	4.44	1.090	68.04	13.18	1.289	16.99
1.030	64.30	4.40	1.218	5.36	1.100	68.67	14.65	1.301	19.05

The factor, *R*, is obtained as follows: Assume a quantity of water loaded with 4.40% of silt by weight. From Table 12, 1 cu ft of water thus laden will weigh 64.30 lb and, hence, 100 cu ft will deposit 64.30 × 4.40, or 282.92 lb., or $\frac{282.92}{52.8}$, or 5,358 cu ft, and $R = \frac{5.358}{440} = 1.218$.

With the foregoing information, Mr. Warren traced the silt load of the Tarka River, discharging into Lake Arthur Reservoir. Over a 3-yr period an average of 2.76% by weight, or an equivalent of 3.31% by volume, was found.

From the published records of the United States Reclamation Service, Mr. Warren assumed that the rolling bed-load was 25% of the suspended load, thus making a total silt load of 4.14% by volume. A silt survey of the reservoir at the end of the 3-yr period showed a silt content of 4.34% by volume, a difference of less than 5 per cent. Although the foregoing result may be fortuitous in some small degree, it constitutes a logical attempt, nevertheless, to take into account the varying degrees of suspended silt carried at different stages during the same flood as well as the varying silt load in different floods resulting from different rates of intensities of rainfall.

The writer has recently had an opportunity of viewing the anti-erosion work conducted both in South Africa and in the United States, and has formed the opinion that this work, judiciously planned and co-ordinated to local circumstances and supplemented by further work in the river channels proper, can reduce the silting of reservoirs materially.

Although it is axiomatic, of course, that a certain degree of erosion will occur, and that silt will always be present, due to ever-present dynamic geological processes, these factors, nevertheless, have been considerably augmented by the careless and haphazard processes of mankind and, in particular, by his agricultural activities. With the opening of new territories, for example, areas have been put under the plow that should never have been plowed. To-day, washes and gullies (or "dongas," as they are known in South Africa), are in evidence, that have widened from 50 to 300 ft "within the living memory of man." The writer has often asked himself the question whether, if the white man had not entered upon his activties in these areas, these selfsame gullies and "dongas" would not still to-day be nearer to the 50-ft width instead of the 300-ft width.

Obviously, it will be impossible both physically and economically to overcome entirely that portion of erosion which can be attributed to Man's activities. A large part, however, can be overcome. The results obtained at Lake McMillan and Zuni Reservoirs, discussed by Mr. Steven, can be considered at least as definite and established indications of what can be accomplished. In the former case, the accidental propagation of tamarasks provided an effective silt trap. In the latter, anti-erosion work of a limited character was conducted on only a portion of the catchment area. In neither of these cases can it be said that the catchments were subjected to a systematic, judicious, and complete program of anti-erosion work, yet in both instances the rate of silting during the past 10 to 15 yr has been reduced to less than 40% of that experienced formerly.

It was with great interest, therefore, that the writer acquainted himself with the principles and aims of the United States Soil Erosion Service and the manner and methods in which these are executed and adapted to each local circumstance. In his opinion, they deserve the serious attention of the profession.

With the careful study that soil erosion is receiving on each of the Soil Erosion Service projects, chiefly from the more agricultural aspects, and the judicious execution of methods to combat these phases, benefits on the resulting silting must be inevitable. If these are next followed up by the more purely engineering aspect of combating erosion in the water channels proper —such as the maintenance of river alignments, the prevention of under-cutting the banks, the formation of vegetative silt traps, the construction of débris basins, as well as the further work of fire protection, the writer does not feel that he is over-optimistic in anticipating a reduction in the silt percentage by volume on many streams to 50% of that occurring at present.

Where engineering works can thus profit, it behooves the profession to pay sincere and serious attention to, and offer constructive co-operation in, the planning and execution of such work. Both in the United States and in South Africa, the writer feels, there is considerable scope for the Civil Engineer to participate beneficially in the soil erosion aspect of the silt problem.

The writer wishes gratefully to acknowledge the data supplied him by Mr. A. S. Bridgman, Maintenance Engineer of the Sundays River Irrigation Board, in regard to Lake Mentz Reservoir.

HERMAN STABLER,[38] M. AM. SOC. C. E. (by letter).—The author has performed a real service to water-supply engineers by making available for ready reference such a mass of quantitative information on the silting of reservoirs and the suspended matter carried by streams. His statement of the silt problem and his discussion of the origin, transportation, and control of silt and of sedimentation processes include a summarization of facts and principles, largely devoid of expressions of opinion, that serves to round out a general picture of the silt problem in a manner both interesting and illuminating. In his discussion of the origin of silt the author touches on geology but, in the writer's opinion, gives it too little emphasis. As defined by the author, silt is stream-borne material derived from the disintegration of rocks. Two processes, weathering (disintegration in place) and corrasion (the tearing away or placing in motion of disintegrated material) are involved in the origin of silt, and the speed of the first of these processes is materially affected by the nature of the country rock. Igneous rocks, in general, are hard, dense, and crystalline; and they weather slowly. The older sedimentary rocks are likewise relatively dense and offer resistance to weathering. The younger sedimentary deposits, particularly recently laid alluvium, are especially susceptible to rapid weathering. Consequently, other things being equal, regions of igneous and precarboniferous rocks are regions of clear-water streams, and regions of recent sedimentaries and valleys filled with alluvial deposits are most likely to give rise to streams heavily laden with silt.

Among the younger sedimentary rocks, differences of texture and cementation are reflected by differences in speed of weathering. Loosely cemented sandstones and friable sandy shales are readily susceptible to weathering and corrasion and are prolific producers of silt.

The chemical composition of rock material is likewise a factor in the silt problem. Rocks that contain high percentages of aluminum silicate weather into clays with fine flaky particles readily susceptible to corrasion and water transportation. Regions of such rocks are likely to be regions of cloudy although not necessarily heavily silt-laden streams.

---

[38] Chf., Conservation Branch, U. S. Geological Survey, Washington, D. C.

The geologic mission of rain and other forms of precipitation, from the moment they strike the earth, is to wear the land surface down to the level of the sea. This is accomplished mainly by weathering and corrasion, by solution, and by water transportation. In some regions of the United States more material is carried by streams in solution than as silt. In other sections the opposite is true. By and large the silt load of the streams of the United States is several times as great as the load carried in solution, but the latter is by no means an unimportant factor.

The relative speed of weathering and of removal and transportation of the weathered material, depending primarily on geology, topography, and climate, is a factor in the silt problem. In some regions streams run clear because little transportable material is available for water to move and only extraordinary storms and floods can muddy the waters. In other regions relatively gentle rains are sufficient to place in motion a wealth of weathered material awaiting only the means of transportation.

Vegetation, an incident of climate, is an important factor in the weathering of rocks and in the availability of weathered material for water transportation. By disruptive action of roots and chemical action of organic solvents vegetation aids weathering and adds to the volume of material suitable for transportation as silt and to the dissolved load of streams. By protection of the land surface from action of wind and water it retards or prevents silty material from corrasion and thus tends to avoid the overloading of streams with suspended matter. Cultivation of field crops artificially aids weathering and accelerates the speed of the natural process. Road building, the herding of stock, lumbering, and a multitude of other activities of Man that scar the earth's surface also speed up the natural process of weathering. Most of these activities are essential to human occupation of the land but some of them may be modified so as to minimize their effect on weathering and still retain their beneficial character. On the other hand, works of Man, such as buildings, streets, and paved roads, substantially prevent weathering whereas his river-regulating works and consumptive uses of water tend to decrease the power and quantity of water that may serve to transport silt and other rock débris. After all, Man's activities, although by no means a negligible factor in the silt problem, must be considered as incidental. Wisely guided, Man will undertake, when practicable, to diminish the removal of material valuable *in situ* to places where it will be deleterious, and to direct the deposition of transported silt at places where it may serve a useful purpose. In attempting to abolish the silt problem Man can be but a Don Quixote tilting at the windmills of Nature.

In attacking the silt problem, should the energies of Man be directed toward prevention or cure? Rather obviously good productive soil in a farming region should be maintained in place for agricultural use so far as practicable. In this case prevention pays, regardless of the silt problem; but it is not so clear that great effort should be made to retain in place the surface material of non-agricultural regions. Regulation of grazing to maintain a maximum permanent useful vegetable cover for forage purposes is itself a profitable conservation measure, and, incidentally, will tend toward silt prevention. This is a practicable measure of silt prevention that may

reasonably be undertaken in a relatively arid or non-agricultural region. To be practicable, however, it should be undertaken primarily in the interests of the stock industry rather than for the purpose of limiting the silt load of streams. Otherwise, costs are likely to exceed the values conserved.

The Colorado River occupies one of the major stream basins in the United States and has silt problems perhaps in greater degree than any other major stream of the country. Its problems of water supply, water utilization, land use, and silt have interested the writer for many years. Most of the extensive surveys of its stream channels, reservoir sites, and dam sites made by the U. S. Geological Survey in the two decades, 1915–1935, were under his general direction. The quality-of-water surveys (determination of daily silt load and dissolved mineral load of the Colorado and of its more important tributaries for a period continuous from 1929, which were made largely by C. S. Howard and S. K. Love under the direction of W. D. Collins, of the Geological Survey) were instigated by him and he has studied their results with interest. These researches, basic to land and water planning, although still inadequate to supply full information, afford probably the best available basis for the study of the silt problems of a large river in the United States. A brief consideration of some of their results will serve by example to throw light on some of the problems discussed by Mr. Stevens. Fig. 10 is a map showing the subdivisions above the principal gauging stations of the Colorado River Basin and Table 13 shows some of the characteristics of these

subdivisions above Grand Canyon, with special reference to the silt load. The lettered subdivisions are identified as follows:

A = the basin of Green River above Green River, Utah.
B = the basin of the Colorado River above Cisco, Utah.
C = the basin of San Juan River above Goodridge, Utah.
D = the basin of the Little Colorado, Paria, and other tributaries of the Colorado River between Lee's Ferry and Grand Canyon, Ariz.
E = the basin of the Colorado River and tributaries between Lee's Ferry, Ariz., and Green River, Cisco, and Goodridge, Utah, including San Rafael, Fremont, and Escalante Rivers.
F = the basin of the Colorado River from Grand Canyon, Ariz., to Green River, Cisco, and Goodridge, Utah.
G = the basin of the Colorado River above Grand Canyon, Ariz.

In Table 13, the information on area, surface geology, palatable cover, run-off, and silt are from records of the Geological Survey; that on rainfall, from the records of the Weather Bureau; that on population, stock population, and area irrigated from the Bureau of the Census, and that on vegetable cover from the vegetation map of the United States by H. L. Shantz, of the Bureau of Plant Industry. The 5-yr period considered is from October, 1929, to September, 1934, inclusive. Acknowledgment is made of assistance by J. C. Miller, C. E. Nordeen, Assoc. M. Am. Soc. C. E., and Depue Falck, all of the Conservation Branch of the Geological Survey, in the compilation of the information.

Inspection of Table 13 shows that, for the period considered (which includes a year of high rainfall and run-off, a year of low rainfall and run-off, and, as a whole, is not far from an average 5-yr period) about 77% of the water and 20% of the silt at Grand Canyon came from the basin above Green River and Cisco, Utah, which comprises 46.2% of the entire area of the basin above Grand Canyon (see Subdivisions *A* and *B*, Table 13); and that less than 8% of the water and more than 60% of the silt came from 36% of the basin's area, situated below Green River, Cisco, and Goodridge, Utah, and above Grand Canyon, Ariz. (see Subdivision *F*). Properly belonging to this region of low run-off and heavy silt load is about one-half the area related to Subdivision *C*, or approximately that part of the San Juan Basin above Goodridge that is situated in Arizona, New Mexico, and Utah. Including this part of the San Juan Basin it is probable that what is commonly known as the plateau region of the Colorado, comprising an area of 60 000 to 65 000 sq miles, contributes less than 10% of the water and more than 75% of the silt load recorded at the Grand Canyon gauging station. Clearly, if silt prevention on the Colorado is a worthy objective, intensive study should be made of the origin, and the possibilities of the prevention of silt derived from this plateau region of the basin. Referring to Table 13, it is evident that this is, relatively, a region of Triassic and Jurassic rocks—loosely cemented sandstones and sandy friable shales—and to these rocks must be attributed the origin of most of the silt.

The plateau region has a low rainfall. One-half the area has an annual rainfall of 6 to 10 in. per yr, 15% has a rainfall of less than 6 in.; and the average for the 5-yr period considered is 9.72 in. The distribution of the rainfall is of importance, and the records show that, substantially, it all occurs in one to six storms during the year. These desert storms are torrential in character, well adapted to corrasion of the rather finely divided weathered material that abounds in the region.

To the arid climate may be attributed the excess of weathered material awaiting transportation and to the torrential character of the storms, the heavy though sporadic flows of silt.

The plateau region has a cover of brush, grass, junipers, and piñon, there being little timber and that is confined to the mountainous outer rim of the basin. The palatable cover is light, being confined to brush interspersed with grass and weeds, occurring as single plants, and the stock and human population is low. In small areas there is a grassy vegetational aspect but in the main the region has the appearance of a desert with vast expanses of bare rock and sand. Probably 90% of the surface of the region is devoid of vegetation. The irrigated area is small and confined almost entirely to the head-waters of streams. It is a land of stock ranges that will furnish year-round feed supply for less than 225 000 cattle, or the equivalent in other stock. The sparseness of vegetation permits the torrential rains to do their work with a minimum of hindrance.

What measures of silt prevention can be undertaken to advantage in such a region? Artifical stimulation of vegetable growth on 60 000 sq miles of surface now devoid of cover and more than one-half of which has rainfall of less than 10 in., is a stupendous, and a hopeless, task. Could it be accomplished to an appreciable degree there is no doubt that the results would be beneficial. There is no lack of fertility, no lack of seeds in the ground. After every soaking rain grass and weeds spring up in abundance, wither, and die. Moisture alone is needed, and moisture it is impracticable for Man to supply. Already 96% of the scant precipitation is devoted to evaporation and transpiration. Only by decreasing the former can much additional moisture be conserved for beneficial use. Stimulation of vegetable cover by regulation or grazing operations is worthy of consideration. Total exclusion of stock from the region for a time would encourage stronger root growth, heavier crowns, and a full opportunity for natural reseeding. This would be beneficial, but how much of the 190 000 000 tons of silt per yr contributed by the plateau region would it keep from the river and for how long and at what cost? The principal cost would be the annual loss of forage valued at about $1 500 000. To this would be added the administrative expense of excluding stock. An annual cost of $2 000 000 might be justified if 10% of the silt could be prevented from reaching Boulder Reservoir and it were worth $150 to $200 per yr to maintain an acre-foot of reservoir capacity. Total exclusion of stock would be impossible because of the human relations involved. Over considerable parts of the area, in the Navajo Indian reservations, for example, stock raising is practically the entire source of livelihood for the people. Nevertheless, the principle of reducing stock population is worthy of consideration, and it is reasonably assured that, where possible, limitation of grazing to that compatible with maintenance of normal cover, would prove profitable to the local stock industry and to some slight degree lengthen the life of reservoirs on the streams below. Increased vegetable growth, of course, would deplete the water supply.

Since the transporting power of flowing water is required to convey it to perennial streams, a second method of preventing silt, would be to conserve the water supply of the plateau region so far as practicable for irrigation or other consumptive use within that region. If the value of the water of the plateau region is $2 per acre-ft for irrigation in the Lower Colorado Basin and 25 cents per acre-ft for the development of power in the canyons, a total value of the order of magnitude of $3 000 000 per yr is indicated. Exclusion of this water from the main river, even without beneficial use in the plateau region on the basis of such an assumed value, would cost at the rate of less than 2 cents per ton of silt excluded with it—far less than the cost of maintaining reservoir capacity by operations at the side under any known method. Reservoir capacity could thus be maintained at a cost of only $20 to $30 per acre-ft per yr. It seems rather clear that the development of beneficial consumptive uses of water in the plateau region should be encouraged to the utmost for whatever effects in silt prevention may result.

A third method of holding silt in the plateau region would be through the construction of detention reservoirs and spreading works. There are many good and some very large reservoir sites in the region. Eventually, many of them will be developed. They could serve to retard the flow of silt to the Colorado although its eventual movement could not be thus prevented. The effective life of such reservoirs would be rather short but the cost of many could doubtless be justified by their beneficial effects in conservation of water and retardation of silt movement. Theoretically, at least, spreading works have merit. If 1 in. of torrential rainfall on 1 000 acres could be spread to 0.01 in. on 100 000 acres, serious silt movement could be prevented. In the process, local vegetable growth would be encouraged and flow of water to the Colorado prevented. Doubtless there are favorable localities in the plateau region for works of such character.

Summarizing, regulation of grazing, development of beneficial consumptive use of water, and construction of reservoirs and spreading works in the plateau region all seem to the writer to merit consideration as means of withholding silt from the Colorado River. He would urge that before expending large sums of money in any such undertaking economic benefits commensurate with the costs be reasonably well assured, full consideration being given to the limitations imposed by the value of storage capacity in reservoirs below and the capitalized cost of maintaining such capacity by operations at the reservoirs. He ventures the opinion, based on personal knowledge of the physiography of the plateaus herein considered, that no practicable means will be found for holding back permanently from the Colorado more than a minor percentage of the silt load derived from the sandstones and shales of the region. It is his firm belief that after all reasonable preventive measures have been exhausted, a now unknown cure for the silt problem will have to be developed, or the inexorable geologic processes that give it rise will deplete seriously, within relatively few generations, and will finally destroy the effectiveness, of the water supply systems of the arid Southwest. It should be recognized, however, that the processes of silt accumulation and deposition have been generally beneficial to mankind. The best agricultural regions of the country are the result of Nature's solution of former silt problems. In the course of geologic time, in the arid Southwest, as elsewhere, the relatively useless sands and clays of the uplands may be expected to contribute their share to the building up of the fertile loams of rich agricultural valleys. Man must adjust his activities to Nature.

N. C. Grover,[39] M. Am. Soc. C. E. (by letter).—The silt problems of the Colorado River at the Boulder Dam are treated in this paper. Some up-to-date information has been obtained as to the effect of this dam on the silt regimen of the river, in connection with the regular activities of the U. S. Geological Survey in its program of measuring and recording the flow of surface streams. Among the 3 000 gauging stations operated, the program includes, of course, a group of stations in the Colorado River Basin. Because of the importance of silt in connection with the utility of the Colorado River, detailed silt studies were undertaken in 1925. Continuous records of the silt content of the water are kept at several of the gauging stations, including those at Grand Canyon, Willow Beach, and Topock, in Arizona.

Fig. 11(*a*) shows the quantities of silt, in millions of tons, carried by the river during each month, from January to June, 1935, at these three gauging stations. Fig. 11(*b*) shows the quantities of water, in acre-feet, carried during the same months. Grand Canyon station is situated well above the reservoir created by the Boulder Dam; Willow Beach station is 10 miles below the dam; and Topock station is about 115 miles below the dam. The Parker Dam is about 40 miles below Topock and about 155 miles below the Boulder Dam.

The construction and utilization of the Boulder Dam create a situation in the river below that dam that has great interest for engineers. The reservoir which is more than 100 miles long desilts the river so that the discharge through the dam is essentially clear water. This clear water, however, is discharged into, and flows through, a channel of silt and picks up a new load, thereby deepening the channel below the reservoir. The deposition of silt in the Boulder Reservoir and the deepening of the channel below it, of course, were anticipated. The speed with which the new load is acquired has general interest as has also the deposition of the new load in the reservoir formed by the Parker Dam which will rapidly lose its storage capacity. The ultimate silt content of the water as it leaves the Parker Dam will affect the problems related to the diversion into Southern California by the Metropolitan Water District of Southern California.

The Colorado River above the Boulder Dam carries apparently an annual load of, say, 200 000 000 to 300 000 000 tons of silt. This load, which prior to the construction of the dam was carried through to Yuma, essentially unchanged, is now deposited in the reservoir. In the five months between February 1, 1935, when storage in the reservoir began to be effective, and June 30, 1935, the load of silt that was carried past the Willow Beach gauging station amounted to about 4 000 000 tons, derived in part from operations at the dam. At the Topock gauging station the total load of sediment carried in the five months was more than 12 000 000 tons. During the same period the quantity of silt carried into the reservoir above the dam was more than 100 000 000 tons.

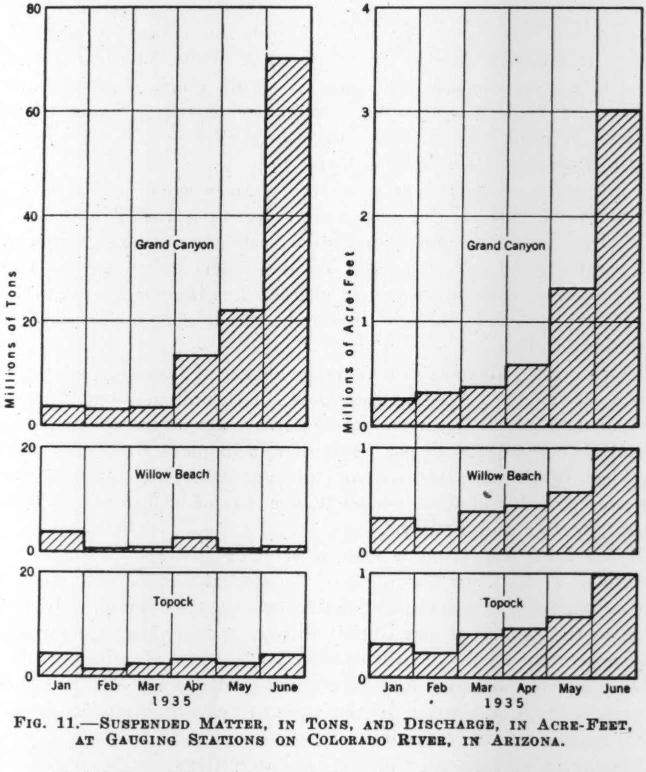

FIG. 11.—SUSPENDED MATTER, IN TONS, AND DISCHARGE, IN ACRE-FEET, AT GAUGING STATIONS ON COLORADO RIVER, IN ARIZONA.

As a result of the pick-up of silt below the dam the channel has already been deepened. At the Willow Beach gauging station the bed was appreciably lower in September, 1935, than it was a few months previously. It is interesting to note also that the particles carried past Willow Beach and Topock are on the average much larger than the particles carried past Grand Canyon and into the reservoir.

Engineers will be interested in following the history of the new and controlled Colorado River, including not only the rates of loss of capacity of the

Boulder and Parker Reservoirs, but also the rate of erosion of the river bed and banks below the Boulder Reservoir. Many years will doubtless pass before the bed, banks, and silt load are stable.

J. C. STEVENS,[40] M. AM. SOC. C. E. (by letter).—A great mass of additional data, particularly on the silting of reservoirs, has appeared in the discussion of the writer's paper. In one paper will now be gathered practically all the basic data regarding the silting of the important reservoirs of the world, as well as summarized data as to the quantity of sediment carried by most of its rivers.

Mr. Nickle mildly chides the writer for not including the excellent data gathered in recent years by the Texas Board of Water Engineers, when as a matter of fact every attempt was made to secure them. Special thanks are due to him for Table 9 containing a summary of the sediment transported at seventeen stations on ten Texas streams, mostly over a 6-yr period, and arranged to conform to the writer's Table 6.

It is interesting to note that of all the stations given in Tables 6 and 9, the maximum concentration of suspended sediment is found in Bad River, at Pierre, S. Dak., where for two consecutive years the sediment averaged more than 38 per thousand. None of the Texas streams listed reached this total even for one year, although the 6-yr average for Double Mountain Fork of Brazos River exceeded 24 per thousand, which shows the next highest concentration of silt.

Mr. Nickle also advances additional evidence of the effect of drying silt in reducing its volume. Medina Reservoir silt shrunk to one-half its original volume and doubled its specific weight in five years of intermittent exposure. The specific weight of 70 lb per cu ft of silt in place for Texas reservoirs, when subject to alternate wetting and drying, is not far different from the writer's average value of 65 lb per cu ft, nor that of 62.5 lb per cu ft adopted by Messrs. Fortier and Blaney.[34]

Professor Lane has given a very interesting historical summary of silt investigations, and a clear statement of the several factors affecting sediment transportation, first to the stream and second by the stream. He also calls attention to the fallacy of the Dupuit theory, namely, that silt is carried in suspension as the result of differences in velocity of adjacent filaments. Turbulence is the real cause, and theory and evidence are now in accord that sediment is held in suspension by the upward velocity components of turbulent flow; that is, by eddy currents.

Mr. Bonner's statement that the capital outlays for reservoirs will be amortized long before they may be rendered useless by silting, and that the solution of the problem may be safely left to posterity, is scarcely a fitting answer to the questions raised. Because of such a major reservoir a civilization comes into being, a virile, complex, pulsating social system. The capital investment in such a civilization may be wiped out and the system destroyed but it can never be amortized in a financial sense.

---

[40] Cons. Hydr. Engr, (Stevens & Koon), Portland, Ore.

A policy of *laissez-faire* is entirely unsuited to the exigencies of the situation. The problem should be squarely faced now and research undertaken with a view to its ultimate solution. Mr. Bisschop cites conditions in South Africa that are now threatening the "very existence of productive centers of population." He states that further extensive developments are being limited to those streams least subject to silting. Lake Mentz on Sundays River (1935) has lost 42% of its capacity in 12 yr. Raising the dam has already begun in order to preserve the civilization that is dependent upon it. Amortization of the capital investment is surely not the answer to this problem. Human institutions must continue.

In Table 10, Professor O'Brien has added a wealth of data on silting of reservoirs from the paper by Dr. Fritz Orth, of which the writer was wholly unaware. This table, however, does not give the silt deposited in terms of the inflow, doubtless because the data were not available. Seven reservoirs are cited that have been completely filled with silt, and fifteen that have lost 50% or more of their original capacity. All of them, however, had original capacities of less than 1% of the annual water supply which means that they were little more than diversion dams. The writer doubts whether any such reservoir could actually lose 100% of its capacity. Table 1 does not show any reservoir as having been entirely filled. As the reservoir fills, more and more of the silt is carried through so that there must be left at least a river channel in the new surface of the reservoir, for which condition all silt passes through.

Mr. Blaney calls attention to the fact that a silty stream or canal is quite free from moss and aquatic plants, and that clarifying such a stream will result in a new source of annoyance, that of moss growth. He states that even if it were possible to clarify the Imperial Valley canals some silt should be left in the water to minimize operation troubles from moss growth.

Mr. Waggoner calls attention to the great fall flood of 1861 that affected the entire Pacific Coast from the Willamette Valley, in Oregon, to Los Angeles, Calif. On December 8, 1861, occurred the largest flood known on the Willamette River. That period was marked by a series of wet years from which the present cycle of equally pronounced dryness has emerged. Obviously, silt depositions and sediment transportation respond with marked fluctuations to these climatic and flood variations.

Mr. Stabler asks whether Man's efforts should be directed toward prevention or cure. It seems quite evident that to show any measure of success the labors of Man must be confined to preventative measures. Of course, he can desilt streams and canals at considerable expense and domestic supplies are necessarily desilted, but these are of secondary importance in the great silt problem. To preserve intact the large agricultural areas he must prevent soil loss. He must learn to prepare the land and cultivate it in such a way as to maintain the soil in place. In the European and Asiatic countries it has been the practice, for centuries, to terrace sloping lands. America has not as yet adopted this practice.

In non-agricultural areas, such as the Western grazing lands, it is doubtful whether extensive structures for soil maintenance are practicable or even desirable except on certain areas that contribute large quantities of silt to reservoired streams.

It is not sufficient merely to construct soil-holding structures. Provision must be made for their continued maintenance; otherwise, the structures deteriorate, and the entire volume of silt accumulated behind them may be loosed by a single storm with much more serious consequences than if it had been allowed to pass in smaller yearly quantities.

Once silt has found its way into a reservoir—except those for domestic supplies—no practicable method has yet been devised of removing it. All Man can hope to do is to reduce the quantity of silt flowing into the reservoir by such means of holding the soil on the area as he may devise. Any structures such as silt dams, bank protection, etc., built for this purpose, should be of permanent type and ample provision should be made for intelligent annual maintenance.

Considerable can be done in stimulating a protective vegetable growth in favorable areas. In unfavorable areas in which the West abounds such efforts are certain to prove futile. Grazing control will have a favorable effect if properly administered although, by and large, the results are likely to prove disappointing. The writer agrees with Mr. Stabler that if the Western grazing lands are managed primarily in the interests of permanency of forage crops for stock production, little more can be hoped for in the way of soil conservation from grazing control.

The data on the Colorado River drainage are most instructive. It would seem that the plateau region deserves extensive study. About 65 000 sq miles contribute 75% of the silt and only 10% of the water supply; yet all that silt is moved by the 10 per cent. If it were practicable to impound that 10% on the area and use it for irrigation instead of allowing it to carry silt into the Colorado, such an irrigated section would pay handsome dividends even if it never marketed a crop. There would be some justification for subsidizing such a project.

Mr. Grover illuminates, with some new data, the effect of desilting the Colorado River at Boulder Reservoir. In 10 miles of canyon the clear waters issuing from the control gates picked up, and carried in suspension, approximately 4 000 000 tons in 5 months. In 115 miles farther this quantity was trebled, and yet during the same period 100 000 000 tons were left in the reservoir.

EFFECT OF SECONDARY STRESSES UPON ULTIMATE STRENGTH

BY JOHN I. PARCEL,[1] M. AM. SOC. C. E., AND
ELDRED B. MURER,[2] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. C. H. SANDBERG, J. D. GEDO, L. E. GRINTER, L. T. EVANS, F. E. FAHY, LAMOTTE GROVER, A. A. EREMIN, AND JOHN I. PARCEL AND ELDRED B. MURER.

SYNOPSIS

An analysis of the action of members of a bridge truss subjected to axial stress and secondary bending that arises from the deflection of the truss in its own plane, is given in this paper. The study is devoted primarily to the question of the effect of secondary stress in reducing the ultimate strength of such members, and, therefore, particular attention is given to the redistribution that occurs when the outer fiber stresses approach the yield point. As a supplementary study, a series of laboratory tests was made to determine the actual behavior of compression members with thin walls subjected to high secondary stresses and loaded to failure.

From the general analysis, and from these tests, it is concluded that for types of members and loading conditions investigated (which are believed to simulate closely the essential conditions for most bridge members), the ultimate strength is practically unaffected, even by high secondary stresses, if, in the case of compression members, the relative wall thickness is maintained at the ratio ordinarily required by the leading standard specifications.

INTRODUCTION

The problem of secondary stresses has occupied a prominent place in the theory of structures since the original investigations of the subject by Winkler,

---

NOTE.—Published in November, 1934, *Proceedings*.

[1] Cons. Engr. (Sverdrup & Parcel), St. Louis, Mo.

[2] Wayland, Mo.

Asimont, Engesser, and Manderla in the late Seventies. A correct and complete analysis was presented by Manderla in 1879.[8] Throughout the half century following, the problem has been the subject of many researches, both analytical and experimental, directed in the main toward clarifying and simplifying the analysis and to its experimental verification. To a considerable extent this effort has been successful. The theory of secondary stress analysis is now generally accepted by most authorities on the same footing as other phases of statically indeterminate stress analysis, and although the numerical calculations involved are tedious, various permissible simplifications have rendered the method quite workable for office design.

American engineers became generally interested in the secondary stress problem much later than European engineers, probably due in some degree to the predominance of the pin-connected truss (for which, if all connections are true hinges, the secondary stresses are negligible) in American practice, and in part to a general distrust of the refinements of statically indeterminate stress analysis which at an earlier period was rather widespread. However, the last two decades (1914 to 1934) have witnessed a striking change in bridge engineering practice. The pin truss is no longer the dominant type; all spans from the smallest to the largest are being built as partly or fully riveted trusses, and the problem of secondary stresses has become a leading question in structural design. Most specifications now require such stresses to be computed for all sub-paneled trusses and for other cases in which there is reason to suspect that they may be large. That for many riveted bridge trusses of the massive type the secondary stresses are high is well established, theoretically and experimentally. In many cases the unit stresses due to secondary bending will reach 60 to 100% of the primary unit stresses, and in certain extreme cases they may exceed these limits.

The present method of providing for secondary stresses in design is subject to rather wide variations. Usually, a considerably increased unit stress (25 to 35% above the normal) is allowed for combined secondary and primary stresses and the member is proportioned by,

$$f = \frac{S}{A} + \frac{Mc}{I} \qquad \text{(1)}$$

in which, f = unit stress; S = primary tension or compression; A = cross-section area; M = bending moment; c = distance from the neutral axis to the extreme fiber; and I = moment of inertia. More commonly, perhaps, a blanket allowance, applied alike to all members, is provided in the prescribed unit stresses.

In a number of monumental riveted bridges (notably the Quebec (cantilever), the Sciotoville (continuous truss), and the Hell Gate (arch) Bridges), elaborate and more or less expensive special devices in fabrication and erection were used to reduce the secondary stresses to a point at which little or no excess material was required.

---

[8] "Die Berechnung der Sekündarspannung welche im einfachen Fachwerke infolge starrer Knotenverbindungen auftreten", *Allgemeine Bauzeitung*, 1880.

While it is thus clear that the possible occurrence of high secondary stresses has been widely recognized and the best standards of practice have required that these shall either be provided for in the design or largely eliminated in fabrication and erection, it does not appear that any considerable attempt has been made to evaluate the effect of secondary stress upon the actual ultimate strength of a member.

It is clear that the action of combined primary and secondary stress is a different phenomenon from that arising from direct stress and flexure due to applied loads. This will be elaborated later in the paper; it may be noted here that (*a*) secondary stresses are not required to maintain the equilibrium of a bridge truss; and (*b*) that they are induced by the relative joint displacements of the structure, which, in turn, are conditioned by the distortion of the truss as a whole; and when these displacements have occurred, there is no further tendency for the stresses to increase. This clearly is quite a different condition from that which obtains in, say, an eccentrically loaded column in which the deflection and moment, at high stresses, increase much faster than the load. This peculiarity of secondary stress action has been noted.[4] Indeed, the opinion has been advanced[5] that even a high percentage of secondary stress, resulting in extreme fiber stresses beyond the proportional limit, will have little effect in reducing the ultimate strength of the truss, since the increased fiber deformations occurring in the neighborhood of the yield point tend largely to relieve the secondary stress. While this extreme view has not been generally accepted by the profession, the subject is believed to merit more attention than it has thus far received.

It is a practically universal principle in structural design that all fiber stresses shall be kept well within the yield point of the material. This, however, is subject to certain exceptions; for example, bearing stresses on rivets and pins are generally permitted to run 50% in excess of the stresses on the main sections. If this specification is sound and if the structure is designed consistently, it means that such local stresses may pass the yield point without endangering the safety of the structure. It is also common practice to permit unit stresses in the stiffening trusses of suspension bridges greatly in excess of the stresses in the towers or in the cable, if comparable material is used in the latter. The logic of this practice is that the stiffening truss is not a main carrying member and that if loaded beyond the yield point, the bridge may still be in no danger of actual failure.

It is scarcely to be presumed that stresses beyond the yield point in either of these cases would ever be regarded as other than undesirable, but since such a condition would not produce structural collapse, it is felt that a smaller margin of safety is permissible than would be the case for the main carrying members.

---

[4] See, for example, "Theorie und Berechnungen der Eisernen Brücken", von F. Bleich, pp. 424–486; discussion by Edward Godfrey, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 193; and Second Progress Report of Special Committee on Steel Column Research, *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 1220 *et seq.* A clear statement of the limitations of secondary stresses will be found in "Modern Framed Structures", by Johnson, Bryan, and Turneaure, Pt. III, p. 14. No use is made of this, however, in the later discussion of the reduction in ultimate strength of columns due to secondary bending (see pp. 57–59).

[5] "Theorie und Berechnungen der Eisernen Brücken", von F. Bleich.

A somewhat similar argument might well be advanced in regard to secondary stresses if it can be shown that, under the normal range of conditions, such stresses do not actually reduce the ultimate carrying power of the members. It may still be regarded as undesirable to have any considerable portion of the section stressed beyond the yield point, but it may be permissible to tolerate much higher limits for such stresses if this in no way endangers the safety of the structure. The remainder of the paper is devoted to a consideration, in some detail, of the relation of secondary stress to ultimate strength.

ANALYSIS OF PROBLEM

General.—Secondary stresses, as considered in this paper, arise from the displacement of the joints in the plane of the truss when the latter is subjected to external loads. If the members are connected by perfectly smooth hinges (and are non-continuous at all joints) no secondary stresses can develop. If, however, the members are connected by riveting (or welding) to gussets so as to form a practically rigid joint, there will be, in general, some degree of restraint at the ends of each member, and corresponding bending moments will be developed. The secondary end moments in any truss member, *m-n*, may be expressed by the well-known slope-deflection equation:[6]

$$M_{mn} = \frac{2\,EI}{L}\,(2\,\theta_m + \theta_n - 3\,R)\;\ldots\ldots\ldots\ldots\ldots(2)$$

in which, θ represents the angular displacements of the joints referred to their original positions, and $R = \left(\frac{\Delta}{L}\right)$, the angular displacement of the line, *m-n*, each in radians. If τ_m and τ_n represent the angles between the end tangents and the line, *m-n*, at *m* and *n*, respectively, the equation for the secondary moment becomes,[7]

$$M_{mn} = \frac{2\,EI}{L}\,(2\,\tau_m + \tau_n)\;\ldots\ldots\ldots\ldots\ldots\ldots(3)$$

which is the form originally proposed by Manderla.

It may be well to call attention here to two basic characteristics of secondary stress action:

(*a*) Even when the secondary unit stress is a high percentage of the primary, the secondary moments offer no appreciable assistance in carrying the loads, and the members are always designed on the basis of full hinge action at the ends.

(*b*) The quantities, θ and R, in Equation (2) are computed from the linear displacements, Δ, of the truss joints, and for all cases of any practical importance they are directly dependent upon the axial distortions of the various truss members and, therefore, are linear functions of the loads.

[6] "Abhandlungen aus dem Gebiete der Technische Mechanik", von O. Mohr, 1906, p. 422 *et seq;* see, also, "Statically Indeterminate Stresses", by John I. Parcel and George A. Maney, Members, Am. Soc. C. E., Chapter VII.

[7] See "Modern Framed Structures", by Johnson, Bryan, and Turneaure, Pt. II, pp. 427–428.

The influence of secondary bending upon the ultimate strength of members depends importantly upon the type of stress acting on the member concerned. The several classes are considered separately in the following discussion.

Tension Members.—In Fig. 1 is shown a tension member, *m-n*, acted upon at the ends by the moments, M_m and M_n. At any point, x, distant from the left end, the moment is (considering clockwise moments positive),

$$M_{(x)} = M_m - \frac{M_m + M_n}{L}\,x - S\,y \ldots\ldots\ldots\ldots\ldots (4)$$

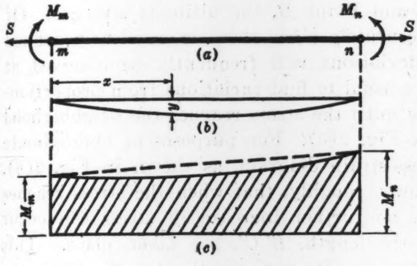

FIG. 1.

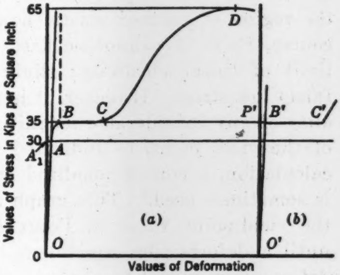

FIG. 2.

For the particular case in which the end moments are equal, and oppositely directed,

$$M = M_m - S\,y \ldots\ldots\ldots\ldots\ldots (5)$$

It is clear that the maximum fiber stress occurs at the end of the member where the larger moment is applied, and (if this is the *m*-end) is equal to,

$$f = f_{\text{axial}} + f_{\text{bending}} = \frac{S}{A} + \frac{M_m\,c}{I} \ldots\ldots\ldots\ldots\ldots (6)$$

Since the relation, $f_b = \dfrac{Mc}{I}$, is derived on the assumption of linear stress variation, Equation (6) is not strictly correct beyond the proportional limit. When the yield point is reached and a large plastic flow takes place, the formula becomes quite inapplicable. The general tendency of the re-adjustment is toward an equalization of the tensile and compressive fiber stresses, respectively, such that a given maximum extreme fiber stress corresponds to a larger resisting moment.

Assume that Equation (3) is valid, then, as long as no stresses exceed the proportional limit, the behavior of the member is practically the same whether the end moments are due to eccentricity of axial loading ($M_m = S\,e_m$; $M_n = S\,e_n$), or to secondary bending. When the region of plastic flow is reached, however, the behavior is fundamentally different. In the first case, while the extreme fiber stress is relieved by the stress-strain re-adjustment, a total resisting moment equal to $S\,e$ must be developed regardless of the state of strain. In the latter case, since it is the tangential displacements that are invariably proportional to the loads (as long as $\frac{S}{A}$ remains within the proportional limit), and since a given angular displacement corresponds to a smaller bending moment when the stresses in the outer fibers approach the yield point, it is clear that within this region the secondary moments increase more slowly than the loads. Some elaboration of this point may be desirable.

Fig. 2(a) is a typical stress deformation curve for mild steel. Point A marks the limit of proportionality; Point B, the yield point; Segment B-C, the region of marked plastic flow; and Point D, the ultimate strength. Of course, Point A cannot be fixed accurately since there is no clearly defined limit of linear elasticity; slight deviations will frequently be observed at fairly low stress. However, it is not usual to find variations from proportionality of any considerable magnitude until the stress reaches the neighborhood of the yield point, as indicated in Fig. 2(a). For purposes of approximate calculation, a conventionalized stress-strain diagram, as shown in Fig. 2(b), is sometimes used.[8] This graph shows, roughly, that when the stress reaches the yield-point value at Point B', no further increase in stress can occur until a deformation equivalent to the length, $B'C'$, has taken place. This deformation may be as much as ten to fifteen times the length, $P'B'$, the value corresponding to linear elasticity.

It is evident from the foregoing relations that in the case of a beam in flexure, if plane sections are assumed to remain plane, the outer fiber cannot be stressed beyond the yield point until the fiber stress, f'_b, over the greater part of the depth of the section has reached this stress limit. Referring to Fig. 3, a beam of symmetrical cross-section is assumed to be loaded so that the outer fiber stress, QP, is just up to the yield point value (Line $O'P'$ in Fig. 2(b)). If the load is further increased, the stress curve takes the form of Area $OPQT$ in Fig. 3. It is particularly to be noted that the contribution to the beam deflection of a vertical slice of thickness, dx,

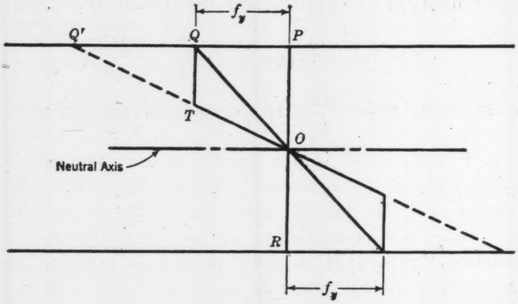

FIG. 3.

at Section *POR,* in the two cases will be in the proportion of *PQ′* to *PQ,* while the moments will have the proportion of *PQTO* to *PQO.* It is clear from this illustration that when the outer fibers reach the yield point, a wide range of beam deflection is possible without any appreciable increase in the extreme fiber stress. Since the angular rotations at the ends of a member can increase no more rapidly than the axial loads, it will be impossible even with high secondary stresses for the extreme fiber stress to exceed the yield-point value without the distortion increasing far beyond any value reasonably to be expected in a truss in service. A simple example may be taken to illustrate the point.

FIG. 5.

It will be assumed that a truss member, *m-n,* of symmetrical cross-section, is subjected at the end, *m,* to an average axial tensile stress $= f_p = \dfrac{S}{A}$, and a secondary stress $= f_b = \dfrac{M_m c}{I}$, in which, M_m is the larger of the secondary end moments. Then, the maximum stress in the member will be at the end, *m,* on the side of the tensile flexural stress and will be given by Equation (6).

The stress graph is indicated by Curve *ABCD* in Fig. 4(*a*). Let it be assumed as a particular case that $f_p = 20\,000$ lb per sq in.; $f_b = 0.75\, f_p = 15\,000$ lb per sq in.; and that the yield-point stress, f_y, is 35 000 lb per sq in. The maximum fiber stress, *AB*, is then just at the limit beyond which plastic flow takes place.

Let it now be assumed that f_p receives an increment of 50%, bringing it to 30 000 lb per sq in. If the linear relation of stress to strain was to hold, f_b would become $1.5 \times 15\,000 = 22\,500$; the total maximum extreme fiber stress would be 52 500; and the stress graph would be the curve, *EFGH*, as shown in Fig. 4. On the other hand, assuming a yield-point stress of 35 000 lb per sq in., it is clear that this value cannot be exceeded until the extreme tensile fiber has suffered a stretch of approximately ten times that corresponding to 35 000 lb per sq in. It is obviously impossible, in a section of ordinary depth, for any such extreme deformation to take place unless the entire section is stressed to the yield point. Therefore, a redistribution of stress must be expected on the tensile side similar to that shown in Fig. 3. Again, it is noted that, as long as the average axial stresses are below the yield point, the tangential deflection angles (τ of Equation (3)) are strictly proportional to the primary unit stresses. In this case (for the small angles involved in the elastic deflections of steel structures), the angle, τ, should be increased in the proportion of $\frac{EO}{AO} = \frac{\alpha'}{\alpha}$. The actual stress graph as modified by the redistribution is the curve, $A'\,F'\,G'\,JK$, as indicated in Fig. 4(*b*). Even if a much higher ratio of $\frac{f_b}{f_p}$ is assumed, the modified stress graph is quite similar. As f_p approaches the yield point still closer, the secondary stress becomes negligibly small as indicated in Fig. 5(*a*), the neutral axis shifting toward the side of compressive flexural stress.

The preceding discussion is based upon the conventionalized stress-strain diagram of Fig. 2(*b*). If the more correct relationships of Fig. 2(*a*) are used, a stress graph similar to that shown in Fig. 5(*b*) results (for f_p slightly below the yield-point stress).

It may be concluded from this analysis that the redistribution of stress which occurs in the neighborhood of the yield point of a ductile material, such as structural steel, will practically nullify any effect of secondary bending.

Fig. 6 shows the elastic curve and moment diagram for a bar under a primary tension, *S*, and equal secondary end moments, *M*. Within the proportional limit the moment diagram appears as Area *abcd* in Fig. 6(*b*). As the extreme fiber stress (which is maximum at the end) passes the proportional limit, and the material begins to flow, a much smaller moment corresponds to a given rotation. Since it is the latter which increases in proportion to the primary stress, when the strain reaches the plastic range, the moment will tend to fall off and the diagram will approach the form, $a'\,b'\,c'\,d'$ (Fig. 6(*d*)). The elastic curve tends to become flat; the curvature (and the region of over-strain) is confined to a short distance at each end (p and q, Fig. 6(c)).

There is precedent for ignoring over-stress of this type when strictly localized. Mention has been made of higher unit stresses allowed in bearing on rivets and pins (see "Introduction"). It may also be noted that most riveted end connections are productive of considerable local over-stress. Reference may also be made to the fact that the presence of a hole in a plate, otherwise uniformly stressed, results in a heavy stress concentration at the edge of the hole. If the diameter of the hole is so small that the width of the plate may be assumed infinite in comparison, analysis shows that the stress at the edge of the hole is three times the average. For normal ratios of diameter to widths, tests have shown stresses 2.3 times the average. However, the re-adjustment that occurs when the highly stressed region reaches the yield point, practically nullifies any effect on the ultimate strength. The two stress graphs are shown in Fig. 7. Below the elastic limit relatively high local stress concentrations must occur in all plates composing riveted members; but, for reasons just stated, these are properly ignored in all normal cases.[*]

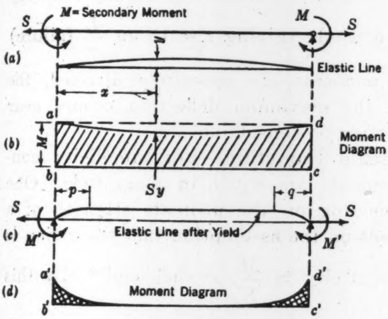

FIG. 6.

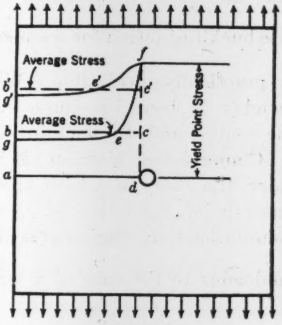

FIG. 7.

If the ultimate strength of a tension bar is understood to be its extreme effective strength as a bridge member, this value is limited to an average stress, $\dfrac{S}{A}$, equal to the yield point of the material. The preceding discussion tends to show that this effective strength is unchanged by any degree of secondary bending that may be expected in a well-designed structure.

Compression Members.—It is well known that flexure combined with compression produces a different behavior in a member from that which occurs under flexure and tension. The axial stress in the latter case tends to decrease the bending where in the former case it increases it; the moment represented by the axial stress times the deflection adds to the normal flexural moment, and in moderately flexible members at high stresses the total moment builds up rapidly. When the more highly stressed fibers pass the proportional limit, and the deflection begins to increase faster than the stress, the member proceeds rapidly to failure.

[*] Reference may be made to "Drang and Zwang", von A. and L. Föppl, pp. 303–305, for presentation of the theory (originally due to Kirsch) ; see, also, "Applied Elasticity", by Timoshenko and Lessells, p. 9 ; and "Theorie und Berechnungen der Eisernen Brücken", von F. Bleich, pp. 249–252.

Most of the compressive chords (and frequently other compression members) in a bridge truss are of a stocky type which, even when subjected to bending stresses of from 50 to 100% of the axial stresses, shows relatively slight deflections from a straight line. The ultimate strength of such members is reached when the average stress over the section reaches, or approaches, the yield point of the material.

In considering the strength of compression members under primary and secondary stresses, the secondary end moments may be either of the same or of opposite signs. When the moments are of the same sign and of nearly the same magnitude, the member is bent into an S-shaped curve, the moment near the center is zero, and the deflections are so small that in any ordinary case buckling action for the member as a whole (giving rise to an $\frac{L}{r}$ failure) is practically negligible. When the moments are oppositely directed, the member is bent in single curvature, the maximum deflection occurs near the center, and the buckling tendency may be considerable.

Compression Member Bent in Single Curvature.—For simplicity consider the case in which the end moments are equal in magnitude. One analysis of the effect of secondary bending on the ultimate strength of a column bent in single curvature proceeds on the assumption that the action is analogous to the case of a virtual eccentricity $= \frac{M}{S}$ at each end.[10] By this method it is found that a considerable reduction in column strength results from the secondary bending. For example, 40% secondary stress reduces the strength of a short column about 28%, assuming the limit to be determined by the maximum fiber stress, $\frac{S}{A} + \frac{Mc}{I}$. A column with a slenderness ratio,

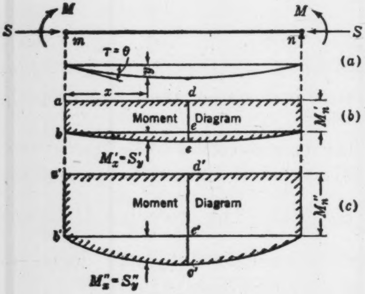

FIG. 8.

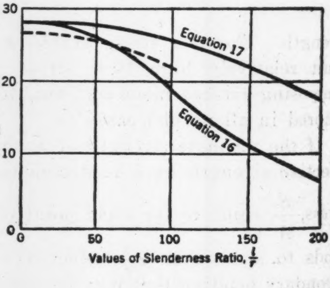

FIG. 9.

---

[10] See "Modern Framed Structures", by Johnson, Bryan, and Turneaure, Pt. II, pp. 57–59.

$\frac{L}{r} = 75$, however, is reduced 35%, due to the added buckling tendency from the end moments.

This theory is open to serious criticism as applied to members that develop any considerable curvature of the central line before failure, because, in such cases, the effect of the moment, $S\,y$, is such as to cause the angle, τ, to increase more rapidly than the loading. This effect is ignored in the common (as distinguished from the exact) theory of secondary stresses.

Moment diagrams for two successive loading stages are shown in Figs. 8(*b*) and 8(*c*). It is clear that: (1) $\frac{\tau_1}{\tau_2} = \frac{\text{Area } abcd}{\text{Area } a'b'c'd'}$; and (2), that these ratios, due to the effect of the moment, $S\,y$, cannot be in the proportion of $\frac{M'_n}{M''_n}$. A more thorough analysis presented elsewhere[11] shows that if $q = \sqrt{\frac{S}{EI}}$, $\phi = \frac{qL}{2}$, and α = percentage of secondary stress,

$$f_b = \alpha\, f_p \frac{\phi}{\sin \phi} \qquad (7)$$

This remarkably simple form admits of a ready comparison with the case in which $M = S\,e$; thus:

$$f_b = \frac{e\,c}{r^2} f_p \sec \phi \qquad (8)$$

from which is derived the ordinary "secant" formula for columns:

$$f_p = \frac{f}{1 + \frac{e\,c}{r^2} \sec \phi} \qquad (9)$$

Similarly, by means of Equation (7):

$$f_p = \frac{f}{1 + \frac{\alpha\,\phi}{\sin \phi}} \qquad (10)$$

It will be found that, since $\frac{\phi}{\sin \phi}$ increases much more slowly than $\sec \phi$, the effect of secondary bending on the buckling of a column is relatively much less than for end moments that increase in direct proportion to the load (as would be the case for eccentric loading). Since $\alpha = \frac{f_b}{f_p}$ in the first case, and $\frac{e\,c}{r^2} = \frac{f_b}{f_p}$ in the latter case, if the same values are taken for these terms (say, α = 25% and f = 36 000) the curves[12] for Equations (9) and (10) will be as shown in Fig. 9.

---

[11] *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 1221 *et seq.*

[12] *Loc. cit.*, p. 1223.

This analysis is not strictly correct in that, while it seeks to make the tangential angle, and not the end moment, proportional to the load, it assumes the correctness of Equation (3). The correct relation, however, is:[13]

$$M_{mn} = \frac{2\,EI}{L}\,(2\,a\,\tau_{mn} + b\,\tau_{nm}) \;\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

in which, a and b are converging infinite series in $q\,L$. Thus,

$$a = 1 + \frac{(q\,L)^2}{30} - \frac{11}{25\,000}\,(qL)^4 + \;\ldots\ldots\ldots\ldots\ldots (12)$$

A rigorous analysis of the problem is possible, but the resulting equations are exceedingly involved and are not readily applied. Their interest is largely academic, since a glance at the graph of the approximate equation in Fig. 9 will show that, for all values of $\frac{L}{r}$ less than 70, the effect of secondary stress on buckling action, measured in this case by the ratio, $\dfrac{1 + 0.25}{1 + \dfrac{0.25\,\phi}{\sin\phi}}$, is slight, and for values less than 50, it is quite negligible. This holds true regardless of the value of a (herein assumed as equal to 25 per cent). Two further facts are to be noted:

(1) Extremely high secondary stresses nearly always occur in members bent in an S-curve. The lower section of the end post in sub-paneled trusses, or trusses with a collision strut, is practically the only exception to this rule.

(2) From a consideration of the properties of bridge trusses and the manner in which secondary stresses arise, it is virtually impossible for a high secondary stress to be developed in a member bent in single curvature which, at the same time, is slender enough to develop any considerable buckling action. The exceptions to this rule are too few to be of importance in ordinary design. With a percentage of secondary stress of 35, or less, the dotted curve on Fig. 9 shows that, as far as buckling is concerned, columns with values of $\frac{L}{r}$ ranging from 50 to 80, have practically the same strength as similar pin-ended columns with $\frac{e\,c}{r^2} = 0.25$.

Compression Members Bent in Double Curvature.—When the secondary end moments are in the same direction, the bar will be bent into an S-curve for which the moment diagram is as shown in Fig. 10. (It is again assumed for simplicity that the moments are equal.)

The deflections in this case will be much smaller than for bending in single curvature, and the points of maximum deflection will fall outside the quarter-points. Obviously, in such a case, the effect of secondary bending on the buckling action of the column as a whole is distinctly favorable since it forces the member to bend in double curvature, and the added bending moment due to axial stress is practically negligible. The high flexural stresses are near the ends of the member, and, in general, the effect of the secondary stresses on ultimate strength is the same as for tension members previously discussed; that is, a high extreme fiber stress occurs over a limited region, and in the neighborhood of the yield point the re-adjustment of stress due to plastic flow reduces the effect to negligible proportions before the average stress reaches the yield point.

---

[13] "Modern Framed Structures", by Johnson, Bryan, and Turneaure, Pt. II, p. 512.

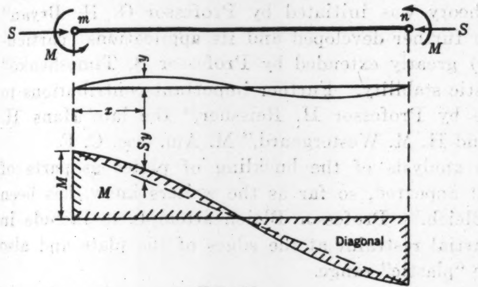

FIG. 10.

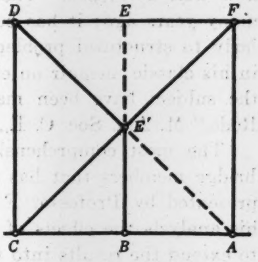

FIG. 11.

Local Buckling in Thin-Walled Compression Members.—Most bridge trusses of the massive type for which the secondary stresses reach high percentages will have relatively stocky chord members $\left(\frac{L}{r} \leqq 40\right)$. Built-up members of such proportions show little or no transverse deflection until the average unit stress passes the proportional limit, and their ultimate strength is ordinarily from 80 to 100% of the yield-point stress of the material. It is generally considered that, for columns of this type, failure is imminent when any considerable part of the section is stressed to the yield point (although the average stress may be considerably less). More often than not the failure occurs through the local buckling of one of the comparatively wide, thin plates that make up the section.

Consider the top chord of a bridge of the conventional box type of section. Assume the material to have a yield point of approximately 35 000 lb per sq in. and the maximum permissible primary unit stress to be 17 000 lb per sq in. The secondary stress will be assumed as 100% of the primary. Under maximum working loads, then, the material on the most stressed side is loaded approximately to the yield point. If the bridge should be subjected to a 50% over-load, and the secondary moments are taken as proportional to the angular changes (that is, if Equation (3) were still to hold), the extreme fiber stress would be 51 000 lb per sq in., although the average would be only one-half this value. It has already been shown that beyond the proportional limit important re-adjustment of stress and strain takes place, resulting in a large percentage decrease in the actual secondary stress. None the less, if the member is assumed to be bent so as to throw the upper side into compression, the entire cover-plate and a portion of the top angles and web (amounting perhaps to 25% of the entire section) will be stressed to the neighborhood of the yield point. It would appear reasonable to suppose that the cover-plate, considered as an independent piece, would be on the verge of buckling as soon as the yield point is reached, and since the high secondary bending causes this state of stress to be reached much sooner than otherwise, it is pertinent to ask whether this may not hasten failure and thus reduce the ultimate strength of the member.

The analysis of the buckling of plates due to loads in their own plane is now well developed. The theory was initiated by Professor G. H. Bryan[14] many years ago; it has been further developed and its applications (particularly to structural problems) greatly extended by Professor S. Timoshenko[15] in his classic memoir on elastic stability. Further important contributions to the subject have been made by Professor H. Reissner,[16] the late Hans H. Rode,[17] M. Am. Soc. C. E., and H. M. Westergaard,[18] M. Am. Soc. C. E.

The most comprehensive analysis of the buckling of plates as parts of bridge members that has yet appeared, so far as the writers know, has been presented by Professor F. Bleich.[19] Professor Bleich attempts to include in his analysis the effects of partial restraint at the edges of the plate and also to extend the results into the "plastic" range.

Some results of these analyses may be summarized briefly. If a plate of length, a, width, b, and thickness, t, is considered to be loaded in the direction of a, with a uniformly distributed compression, $P = f_p\, t\, b$, and restrained against linear (but not angular) displacement along the edges parallel to the loading, Bryan's formula for buckling in a single wave is,

$$f_p = \frac{\pi^2 E}{12\,(1 - m^2)} \left(\frac{t}{b}\right)^2 \left[\frac{a}{b} + \frac{b}{a}\right]^2 \qquad (13)$$

in which, m = Poisson's ratio (usually 0.25 to 0.3 for steel).

Bleich proposes using a variable factor, τ, a function of the stress, f_p, to modify the value of E for stresses beyond the proportional limit. For conditions assumed in Equation (13), he derives,

$$f_p = \frac{\pi^2 E \sqrt{\tau}}{12\,(1 - m^2)} \left(\frac{t}{b}\right)^2 \left[\frac{a}{b \sqrt[4]{\tau}} + \frac{b \sqrt[4]{\tau}}{a}\right]^2 \qquad (14)$$

For $\tau = 1$, this reduces to Bryan's formula.

From Equation (13), for a fixed ratio of $\frac{t}{b}$, f_p will vary with the quantity in the square bracket and will be a maximum for $a = b$, giving,

$$f_p = \frac{\pi^2 E}{3\,(1 - m^2)} \left(\frac{t}{b}\right)^2 \qquad (15)$$

Taking $m = 0.3$, Equation (15) gives 67 900 lb per sq in., and 43 400 lb per sq in., respectively, for $\frac{t}{b} = \frac{1}{40}$ and $\frac{t}{b} = \frac{1}{50}$

If the edges are fully fixed, the foregoing buckling loads are practically doubled. Undoubtedly, the true condition is intermediate between these extremes. These results tend to show that for normal proportions of a compression chord, buckling of the cover-plate will not take place within the elastic limit of the material. Beyond this point, of course, the formula does not apply.

In evaluating his expression for the buckling load in the more general case in which some of the material may be strained beyond the proportional limit, Bleich, after a lengthy analysis, obtains for f_p (in tons per square centimeter),

$$f_p = \frac{\phi}{2} - \sqrt{\frac{\phi^2}{4} - 9.61} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

In which, $\phi = \dfrac{\left(\dfrac{b}{t}\right)^4}{E \times 10^4} + 6.2.$

For $\dfrac{t}{b} = \dfrac{1}{40}$, $f_p = 36\,600$ lb per sq in.; and, for $\dfrac{t}{b} = \dfrac{1}{50}$, $f_p = 32\,800$ lb per sq in. Again, it should be noted that these values are for the case of no edge restraint.

Any attempt to take into account the variation in E beyond the proportional limit is attended with much difficulty; hence, Equation (16) cannot be regarded as more than roughly approximate, and is scarcely applicable in the region of large plastic flow.

In applying the buckling formulas to the secondary stress problem, consideration must be given to the important difference between a plate with freely supported edges, loaded in its plane, and, say, a cover-plate of a chord member under combined primary and secondary stress. In the former case, when the stress reaches, or closely approaches, that corresponding to the point, B, on the stress-strain curve of Fig. 2, any further increase will result in distortions many times as great as those previously sustained. Such distortion has the effect of grossly exaggerating any slight imperfection in material or manufacture, and since no plate is perfectly straight or homogeneous, relatively large transverse deflections are developed which lead to immediate collapse.

In the case of a cover-plate subjected to combined primary and secondary stress causing the extreme fiber to reach the yield-point value, it is equally true that any material increase in the stress will probably result in a buckling failure. As has been shown, however, this increase cannot take place as long as the average stress on the section is well below the yield point, since it must be accompanied by a large plastic flow, and, due to the restraint of the adjacent material, such large flow cannot possibly occur in one part of the section until practically the entire area is stressed to the yield-point region. It appears reasonable to suppose that what actually happens is that when the yield-point stress is reached in the cover-plate, a practically constant state of stress is maintained under increasing load, while the deformation (which in this region of large plastic flow may vary widely with almost no change in the stress) varies only as is required to produce the necessary secondary displacements. As long as the average primary stresses are within the proportional limit, these secondary displacements will increase no faster than the applied loads. In other words, the free flow (accompanying a stress reaching the yield point) which would take place in an independent plate, is restrained to comparatively small limits by the action of the neighboring material in the case of axial stress and secondary bending, and this, it may be expected, will have a large effect in reducing the buckling tendency in the cover-plate.

When the average stress over the section passes the proportional limit, the cover-plate distortion begins to increase rapidly, and somewhere between this and the yield point of the column as a whole, local buckling of the cover may be anticipated.

One further point deserves some emphasis. When the common theory of secondary stresses is applied, it is assumed, of course, that the law of linear elasticity applies and that the effect of bending due to $S\,y$ is negligible. When, therefore, as discussed previously, an average primary stress of 26 000 lb per sq in., and a secondary stress equal to 100% of the primary, are computed for any member, what really happens is that the member is distorted at the end so that the tangential angle is such as would correspond to 26 000 lb per sq in. flexural extreme fiber stress, assuming E to be constant and the effect of axial stress on bending negligibly small. If the stress-strain diagram of Fig. 2(a), is examined, however, it will be noted after the limit of strict proportionality is passed (that is, when E becomes variable and a function of the load), that there is a considerable deviation from linearity before the region of free plastic flow is reached. The actual deformation at Point B (the beginning of marked plastic flow) will ordinarily be equivalent to that which would be produced by a stress of 40 000 to 50 000 lb per sq in., if the material followed the linear stress-strain law. In other words, the variation in E, before the actual yield point is reached, is sufficient to take care of a nominal extreme fiber stress due to combined primary and secondary effects considerably greater than the yield point of the material, and probably equal to any value to be found in well-designed trusses, even of the heaviest and most rigid type.

The possible effect of stresses beyond the elastic limit upon local buckling, especially of the cover-plates in the standard type chord sections, is the one point upon which the deductions from rational analysis are rather indecisive, and, if the preceding analysis is sound, the only manner in which there is any reason to suspect that the ultimate strength of a compression member may be affected appreciably by secondary stress. These facts seemed to justify an experimental study of the phenomena of failure in a built compression member of the box type subjected to a high percentage of secondary stress, with particular emphasis on the behavior of the cover-plate in the region of high local stress. In the following section, an account is presented of a limited group of laboratory tests undertaken to throw some light on this particular phase of the secondary stress problem.

EXPERIMENTAL STUDY

Model Simulation of Conditions.—The experimental study consisted of the testing of four columns of symmetrical section of standard types, giving in all eight separate tests of columns under the action of secondary stress and direct axial, or primary, stress. Column No. 1 was made up in the shop of the Experimental Engineering Laboratory, University of Minnesota, Minneapolis, Minn., and the remaining sections were fabricated in the Minneapolis Plant of the American Bridge Company. All specimens were of relatively small cross-section as the testing machine available was not of sufficient capacity to handle a full-sized normal bridge chord.

Because of the difficulty of simulating the partial fixity of the ends of a member in a riveted truss, introducing as it would the problem of controlling and measuring the induced rotations, all specimens were tested with hinged ends. Such a member is closely analogous to the top chord member in a pin-connected sub-paneled truss with the members continuous over the sub-panel points (see Fig. 11). A truss of this type, while nominally classed as pin-connected, may show high secondary stresses at such places as Point *E*. However, it should be emphasized again, the object of the experiments was to study the behavior of built compression members under high local stress due to combined primary and secondary action. As long as the essential features of such action are maintained, it is immaterial for the purposes of the test whether or not all details correspond to those which obtain in the case of an actual truss member under high secondary stress.

It is true, of course, that ordinarily the highest percentages of secondary stress occur in trusses with fully riveted chords. In Fig. 11, Joint *E′* will deflect about the same amount regardless of the end conditions of Member *D F*. If the end joints are fully riveted, the added stiffness of the member due to the partial restraints at Points *D* and *F* will cause (for approximately constant center deflection) considerably higher secondary stress at Point *E* than would be the case for pin connections. As long as the fundamental characteristics of secondary stress behavior are preserved, however, high stresses, artificially produced, will have the same local effect on a member of given cross-section as if these same stresses were brought about by exact simulation of all the details of riveted truss action. This remark applies also to the method of loading which was followed in the test.

Again referring to Fig. 11, it will be noted that if Member *EE′* is removed, there will be no secondary stress at Point *E*, since this latter is caused by the displacement of Point *E′* relative to Line *DF*. This displacement tends to be transmitted to Point *E*, through Member *EE′* (the blank strut), developing a considerable tension in the latter. The action is identically that of a beam, *DEF*, with a transverse load at Point *E*, with this exception: The deflection of Point *E′* (and, therefore, of Point *E*) is strictly limited by the relative displacement arising from axial distortions, and which may be computed analytically or by means of a Williot diagram. Quite contrary to the case of a free transverse load at Point *E*, when the displacements have reached the prescribed value, Point *E* is rigidly held in position, no further deflection being possible. This is the unique characteristic of secondary stress action. Clearly, it can be simulated accurately in the case of a column by applying the axial loads, together with a certain controlled deflection. If, in such case, one wishes to study the behavior of the member at a given stage of combined primary and secondary stress, it is immaterial whether (*a*) a given primary stress is applied, and then the desired deflection is induced; (*b*) the desired deflection is induced and then the direct stress is applied; or (*c*), the two are developed simultaneously. The second method was followed in this investigation.

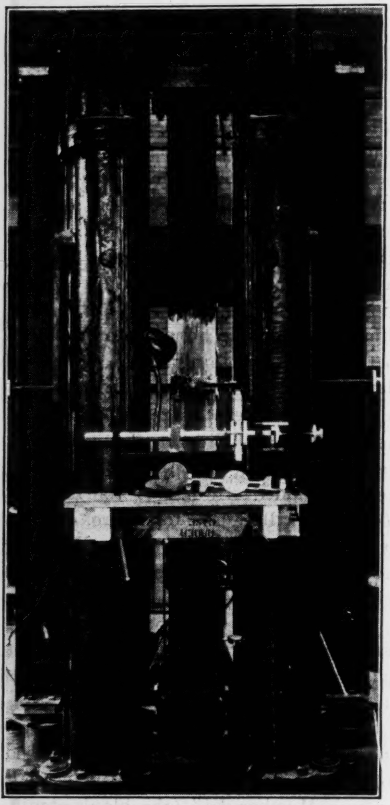

FIG. 12.—SET-UP OF EXPERIMENTS ON SECONDARY STRESSES.

The columns tested were made to conform to the foregoing condition by being subjected to a constant bending deflection and consequent secondary stress as the axial stress was increased. This combination gave maximum effects due to combined secondary and primary stresses at the center line, with primary stresses only acting at the ends. In order to realize this condition the columns tested were placed inside a rectangular frame of rigid I-beam sides with thin flexible ends. The bending deflection of the column was then maintained at a constant value by the use of a toggle extending about the sides of the frame. The flexible end plates were sufficient to transfer the transverse thrust, but not stiff enough to cause appreciable moment on the end of the member or to interfere with the axial loading of the column by the testing machine. In this manner a combination of stresses was maintained in the cover-plate of the column analogous to the combined primary and secondary stresses at the stay connection of Member *DEF* in Fig. 11. The actual amount of the secondary stress was thus dependent upon the transverse deflection given the specimen and was varied somewhat for different sections, depending upon their properties. Reference to the general photograph of the set-up (Fig. 12), and to the detail drawing of Column No. 2 (Fig. 13), will help to clarify the description of the specimen and testing frame.

Column Dimensions and Properties.—Column No. 1, Table 1, was similar to the standard top chord section of a bridge, consisting of plates and angles with a top cover and open bottom (see Fig. 14).[20] Because of the limited capacity of the testing machine and the difficulty of providing the necessary transverse bending force in the toggle, the model was made one-fifth the area

---

[20] The proportions follow closely the top chord of the typical truss given in "Modern Framed Structures", by Johnson, Bryan, and Turneaure, Pt. III, Pl. III.

base plate was provided; otherwise, the details at the center line and ends were the same in both cases. Columns Nos. 2, 3, and 4 were of slightly different section, being made of two standard channels with two cover-plates (closed). Because of the symmetry of the section, two tests could be made from each specimen. They were fabricated in the standard manner using punched holes and $\frac{3}{8}$-in., hot-driven rivets, while Column No. 1 had small cold-driven rivets in drilled holes. The ends of the members were milled to provide full bearing. The properties and detail drawings of the various column sections are shown in Figs. 13 to 16. Column No. 4 was the same as Column No. 3 (Fig. 15) except for the welded bars shown in Fig. 16.

Test Procedure.—The axis of the member was set as nearly vertical in the testing machine as could be done with a hair wire and weight. The pins were placed at the centroid of the section as closely as this could be measured and transferred to the base plate. Pins were flattened on one side to fix the point of rotation and to give a definite value of L in the plane considered. They were supported on cylindrical heads in the other plane to fit them to any angularity between the column ends and the testing machine. The detail drawing of Column No. 2 (Fig. 13) will make the test set-up clear.

The initial loading used in all cases was 1 000 lb and the increments of axial loading were equivalent to 2 500 lb per sq in. on the section for the first test, and 5 000 lb per sq in. for the second test, on each specimen. Strain readings were taken at all increments of loading and, in many cases, loadings were repeated several times to establish the behavior of the member more definitely. Strains were obtained on Column No. 1 by the Whittemore strain-gauge, and on Columns Nos. 2, 3, and 4 by both Huggenberger tensometers and the Whittemore gauge. Consistent deformations were obtained to 0.00001 in. per in., or equivalent stresses of approximately 300 lb per sq in., with the aforementioned apparatus. Gauge lines on Column No. 1 consisted of five 10-in. lines on the compressive face, and six 10-in. lines on the tensile face placed symmetrically about the center line. Gauge lines on Columns Nos. 2, 3, and 4 consisted of one 10-in. line and four 1-in. lines on each face symmetrically placed. (See Fig. 17.)

FIG. 17.—GAUGE LINE DIMENSIONS.

As the deflection of the column was to be maintained at a constant value such that the nominal secondary stress remained constant throughout the range of primary loadings below the material yield point, it was necessary to measure the deflection value accurately. This was accomplished by means of an optical micrometer in the case of Column No. 1 and an electrical contact screw micrometer for Columns Nos. 2, 3, and 4, measuring the deflection between a hair wire and a point on the specimen center line in the web. It must be noted that the actual column deflection was not measured in any case, as the hair wire was not fastened to the point of rotation of the column ends, but to some point on the deflecting structure. This had no effect on the problem because it was only necessary to have a relative value that could be measured and maintained. The deflection was not used directly for stress calculations, but was kept at a constant relative value in order to give a certain nominal secondary stress. In the case of Columns Nos. 2, 3 and 4, the wire was fastened so closely to the point of rotation that approximately the actual deflection values were read, while in the case of Column No. 1 the wire was fastened to the one-tenth points on the specimen. This fastening necessitated a calculation of the elastic curve of the column so that an approximate value of the relative deflection between the one-tenth points and the center would be available. The elastic curve was calculated carefully, and it was noted that little change occurred in the deflection values for a large range of axial loadings. The equation for the elastic curve based on a constant center deflection and variable axial loading takes the following form:

$$y = \frac{\Delta}{\frac{\text{t}\left(\frac{}{}\right)}{q} - \frac{L}{2}} \left[\frac{1}{q}\,\frac{\sin (q\,x)}{\cos\left(\frac{}{2}\right)} - x\right] \ldots\ldots\ldots (17)$$

in which, Δ = center deflection and $q = \sqrt{\frac{}{EI}}$.

It was decided to use a secondary stress of approximately 13 000 lb per sq in. for Column No. 1, Test 1, giving roughly 50% secondary stress at the material yield point. Since this test indicated that such a value was insufficient to cause local failure to develop before the normal ultimate strength of the columns was reached, in all later tests a value of 20 000 lb per sq in. was used in an attempt to produce a more marked local effect. Using approximately a secondary stress of 20 000 lb per sq in., the required deflection of the column was calculated and this value used as a basis for the approximate measurement in the tests. Table 2 gives calculated deflections and lateral loads corresponding to required secondary stress values. (The action of the column under lateral load was that of a simple beam prior to the application of axial loadings.)

TABLE 2.—CALCULATED LATERAL LOADS AND DEFLECTIONS FOR ASSUMED SECONDARY STRESS

Column No.	Lateral load, P, in pounds	Displacement, Δ, in inches	Stress, f', in pounds per square inch
1	4 750	0.0900	13 250
2	19 200	0.2685	21 300
3	16 200	0.2556	20 000
4	16 200+	0.2556	20 000

During the testing operations the deflection was checked and corrected if necessary at each increment of axial loading, and when the axial stress reached a value sufficient to reduce appreciably the lateral force necessary to maintain the deflection, the stability of the columns was assured by stressing the toggle on the compressive face, thereby preventing sudden $\frac{L}{r}$ - failure in the direction of the imposed deflection. This additional toggle was also used in adjusting the deflection after the bending resistance of the column had been reduced due to plastic flow, and the original transverse force would have caused more than the required deflection.

Before testing, the specimen was painted with a dilute solution of plaster of Paris and water to make the strain lines visible. These are clearly shown in Fig. 19. The strain lines were recorded and sketched as they appeared during the test and a typical set is shown in Fig 18, with Table 3. Determination of the transverse force necessary to maintain the required deflection was accomplished by strain measurements on the toggle-bars and subsequent calculation of the force transmitted. As an indication of the reduction in moment and consequent reduction in the transverse force, *P*, as the material in the column cover-plate approached the yield point, and stress re-adjustment took place, the measured *P*-values are given in Table 4 for Columns Nos. 2 and 3.

For the purpose of this paper, it was not considered desirable to reproduce all the test data in detail. Tables 5 and 6 present the data from Column No. 1, Test 2, and Column No. 2, Test 3, showing deformations, in millionths of an inch per inch, for various axial loadings. These data are presented as typical examples of all eight tests, there being remarkably close agreement in all cases.

† Readings discontinued at this point.

The ultimate loads for Tests 2 and 3 were 167 800 lb and 381 800 lb, respectively, corresponding to a stress of 42 800 lb per sq in. and 35 700 lb per sq in. In Column No. 1 (see Table 5), failure occurred first in the web, near the base, after which the cover-plate buckled. A set of 80 millionths of an in. per in, is shown on the tension side, which indicates that even this side was stressed beyond the elastic limit (compression forces).

As it was necessary to conduct a part of the test with some of the material stressed beyond the elastic limit, the characteristic stress-strain curves for the material were obtained in order that an estimate of the stress increase after passing the elastic limit could be made. A piece of material from the same rolling was used to determine the relations for Column No. 1 (see Fig. 20, Curve *A*). For Columns Nos. 2, 3, and 4, a coupon was cut from the cover-plate of Column No. 2 (see Fig. 20, Curves *B* and *C*). The modulus of elasticity is seen to check closely that determined from the columns. It is noted that the curve is nearly horizontal beyond the proportional limit even though the deformation was several times that of the yield-point stress. On this basis the stress carried by any material beyond the yield point was assumed to be a constant and of intensity equal to the yield-point value.

An inspection of Fig. 20 shows that the increase in stress after the proportional limit is reached and before the curve becomes so flat as to make the stress nearly constant is approximately 3 500 lb per sq in. for Column No. 1 and from 2 500 to 3 000 lb per sq in. for the remaining columns. The proportional limit for the material of Column No. 1 was taken to be 39 000 lb per sq in., which gave a value of 42 500 lb per sq in. for maximum stress, a close check on the ultimate strength of the column. Similarly, the proportional limit of the materials of Columns Nos. 2 to 4, inclusive, was found to be 32 500 lb per sq in., with a maximum value of approximately 35 000 lb per sq in., which is also a good check on the ultimate strength of the columns.

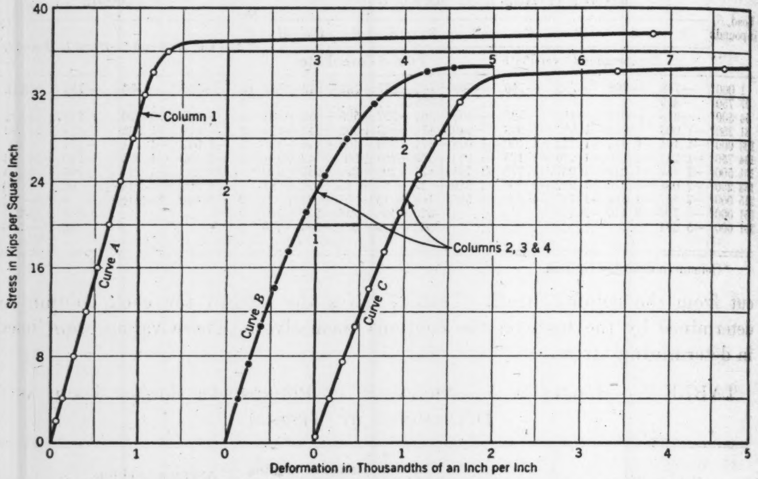

FIG. 20.—STRESS-STRAIN CURVES FOR MATERIAL IN TEST COLUMNS.

In computing stresses in the cover-plates from the measured strains, it must be remembered that the deformations obtained by the Whittemore gauge are average values over a 10-in. gauge length. (The Huggenberger gauges have 1-in. gauge lengths.) When the column is deflected under transverse moments these deformations do not represent the maximum strains, inasmuch as the strains due to bending vary from a maximum at mid-length to zero at the end of the column. This results in an appreciable change in the resultant unit deformation within the gauge length of the instrument when long gauge lengths are used. An approximation to the difference between the maximum and the average reading may be estimated on the basis of the moment change. Since the moment is nearly proportional to the distance from the end of the column (concentrated load), the moment diagram approximates a triangle and the deformation decrease is proportional to the average decrease in length from the end. In this case ($L = 128.2$ in. for Columns Nos. 2, 3, and 4), the percentage of change equals $\dfrac{\dfrac{5}{2} \times 100}{\dfrac{128.2}{2}} = 3.9.$

Since the deformation from bending was approximately one-half the total, the error involved in neglecting this factor was approximately 2 per cent. As this value is approximately the probable error in reading, loading, and sectional area, it has been neglected in the curves and stress calculations.

Tables 8 and 9 give the stresses for the two tests as determined from the strains given in Tables 5 and 6 and the moduli of elasticity given in Table 7. After the proportional limit has been passed these stresses are incorrect, and the values are only given to show the nominal stresses that would occur in the plate were Hooke's law still operative. The actual values after the elastic limit has been passed, have been discussed previously.

Re-Adjustment in Stress-Strain Relations.— By plotting the measured stresses on the compressive and tensile faces of the column with respect to a fixed line, a graph of stress distribution across the section was obtained. After the proportional limit is passed on the compressive side this graph is no longer a straight line, and, finally, the part of the curve beyond the material yield point becomes asymptotic to the line representing the ultimate unit strength of the column. The gauge lines used in determining the stresses plotted are given on the graphs shown, so that by reference to Fig. 17, the section referred to will be readily identified. Fig. 21 contains examples of these curves for the data of Tables 8 and 9. It should be emphasized again that the curves presented are nearly identical with those of the other tests.

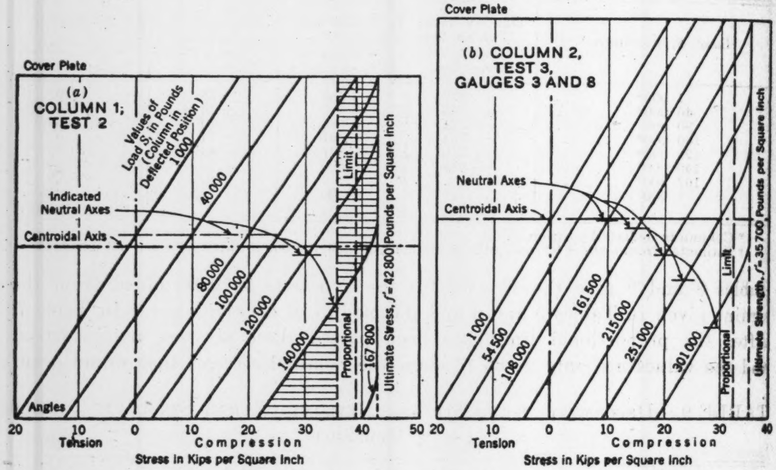

FIG. 21.—STRESS DISTRIBUTION (AVERAGE READINGS), COVER-PLATES AND BOTTOM ANGLES.

In Fig. 21(*a*), the curve for the 140 000-lb load has been shaded for the purpose of illustrating the re-adjustment more clearly. This curve shows a stress on the tensile face of 22 000 lb per sq in. in compression, and if the straight portion were extended, would give a stress of approximately 57 000 lb per sq. in. on the compressive face. Since the yield point was determined as 39 000 lb per sq in., and the ultimate testing strength as 42 800 lb per sq in., it is evident that such a high nominal stress cannot occur and that a re-adjustment consequent upon plastic flow must take place as indicated by curvature of the graph. The direction of the straight portion was made parallel, in all cases, to the last curve on which the end points were within the elastic limit. The shaded area represents the bending stress over the section, while the heavy dashed line (which intersects the curve at the indicated neutral axis) shows the axial stress. Fig. 21(*a*) shows this section to be almost completely under the action of axial stress at failing load.

Cover-Plate Stiffeners.—The views of Column No. 3, in Figs. 19(*e*) and 19(*f*) show a buckle occurring at the point of critical stress. (This column had a cover-plate relatively thinner than permitted by standard specifications.) The significance of this action will be discussed later. It will suffice here to note that it seemed worth while to investigate the feasibility of the application of a simple stiffening device to the plate. This was done in the case of Column No. 4 which (see Fig. 16) is a duplicate of Column No. 3, except for the plate stiffeners. No special attempt was made to develop the most practical device for commercial use; nor was any attempt made to follow a welding schedule and to reduce heating effects. The object in view was to test the effectiveness of the simplest type of stiffeners in supporting the wide, thin cover-plate when buckling was impending, so that it might suffer a certain amount of plastic deformation without "dishing" out of its original shape. Since little force is necessary to restrain such a plate from bending, small sections were welded to the cover-plate to give the necessary support against displacement normal to its plane, and thus, in effect, to cut down the free width. It was felt that if a simple device could be applied which would make the thin plate as resistant to buckling as a thicker one, this would be a desirable result regardless of the fact that in the specimens tested the plate buckling did not materially reduce the ultimate strength.

Discussion of Results

For specimens of the dimensions and character used in this study, it would be reasonable to expect that a high degree of integrity of section would be maintained under an intensity of stress corresponding to ordinary working values. On Column No. 1, however, a noticeable slip was observed between the web and the flange. The deformation difference amounted to approximately 30% of the bending strain. For the plate and channel sections used in Columns Nos. 2, 3, and 4, no direct measurement of the slip was made as in Column No. 1. However, since the stress-deflection values checked rather closely, it was concluded that no appreciable slip had occurred.

Fig. 19 shows strain lines occurring on both flanges of the specimen and across the web joining the two flanges. Since the nominal secondary stress due to bending was approximately 20 000 lb per sq in., such strain lines could not have occurred on the tensile side, under elastic conditions, until the average axial loading had reached 52 000 lb per sq in. (the yield point being approximately 32 000 lb per sq in.). As the ultimate axial load was approximately 35 000 lb per sq in., it is evident that the secondary bending was relieved by the plastic condition on the compressive face, which permitted a given angular change to take place with a much lower extreme fiber stress. This angular change, in turn, reduced the tensile flexural stress, with the result that the stresses due to the axial load of 35 000 lb per sq in. were sufficient to cause appreciable yield. That a complete re-adjustment resulting in a nearly uniform distribution over the section was the final state of stress, is evident from an examination of the strain lines on the tensile cover-plate, which, while nominally holding a stress of 15 000 lb per sq in., passed the elastic limit despite the fact that the ultimate average axial stress was only a little greater than the value of the elastic limit as measured.

The stress distribution curves (of which Fig. 21 is characteristic) bear out further the action indicated by Fig. 19. They show a redistribution of stress within the plastic range in complete agreement with the theoretical analysis presented previously. As the loading is increased, the neutral axis is progressively lowered until it lies near the edge of the section; the bending stresses become negligible and the distribution is nearly uniform over the entire section.

Referring to Fig. 2 and recalling that the plastic deformation in the neighborhood of the yield point is approximately fifteen times the elastic deformation at the proportional limit, it is obvious that it would require far greater secondary bending than the value developed in the test to cause the extreme fiber stress to exceed the yield point; that is, to reach Point C, Fig. 2. Assuming elastic behavior, the test loading gave a nominal maximum extreme fiber stress of 55 000 lb per sq in. The corresponding deformation, however, was less than twice the value occurring at the proportional limit; for the stress to reach the value, C, would require six to eight times this deformation.

Another point to be emphasized is the fact that if the stress is assumed to remain at an approximately constant value in the compressive face while the yield is traversing the flat part of the curve of Fig. 2(*b*), even though the material flows freely without appreciable increase in stress, it can deform only to a limited extent because of the action of the remainder of the section; and, until such time as the entire section is approaching the yield point, it will deform only enough to get relief from additional stress, while continuing to hold its yield-point value. This condition is radically different from that of a specimen subjected to a stress that cannot be relieved in intensity by a slight yield.

In examining the distribution curves it is of interest to note that when yield on the compressive face is shown by a curvature of the graph, the increment of stress received by the tensile plate for uniform increments of loading is constantly increasing. A measurement of this change gives an idea of the "relief" of the bending stresses as plastic flow permits the column to assume the deflected position that originally caused the secondary stresses. A further estimate of this relief is obtained from Table 4, which gives the measured transverse force, P, necessary to cause the original deflection and its value during the test as plastic flow was reached. The reduction shown is quite marked. The amount of bending stress remaining (as shown by the stress diagrams of Fig. 21) may be checked by comparison between the permanent set in the column after test and the deflection used for secondary stress, the difference in deflection being used in an approximate calculation of the bending stresses necessary to cause this small deflection. The values of the permanent set are given in Table 10.

An examination of the data presented in Tables 8 and 9, and in the plotted graphs, shows a deformation along the center line of the column somewhat greater than that at the rivet lines. Since the bending stresses are transmitted to the plate at the rivet lines, such a distribution would appear, at first glance, to be contrary to what should be expected. As a possible partial explanation, it was noted that on all specimens a marked transverse curvature of the cover-plate (concave outward) developed under bending action alone, somewhat analogous to that commonly observed in wide flanged I-sections. This dishing inward was largely confined to the region of high flexural stress, and apparently resulted in an appreciable accentuation, locally, of the longitudinal curvature of the plate, which would be reflected in a somewhat higher deformation in the outside fibers along the center line of the column, where the gauge readings were taken.

TABLE 10.—PERMANENT SETS AND MAXIMUM LOADS

Column No.	Test	Deflection produced, in inches	Maximum load, S, in pounds (column in deflected position)	Permanent set, in inches
1..........	1	0.0900	140 000	0.0796
1..........	2	......	167 800	0.2033
2..........	3	0.2685	339 000	0.2055
2..........	4	0.2685	381 800	......
3..........	5	0.2556	271 000	0.1530
3..........	6	0.2556	344 000	0.2360
4..........	7	0.2556	295 500	0.1945
4..........	8	0.2556	305 000	0.2314

It is worthy of note that this dishing action has one distinctly favorable effect on the ultimate buckling strength of the cover in that, by directing the buckling inwardly, it reduces the unsupported width of the plate from the distance between the rivet lines to a value considerably less—probably almost the clear distance between the backs of angles or channels. It will also be observed that the bending of the column as a whole has a tendency to direct the buckling of the cover-plate inward. These facts are of considerable significance for cases in which local buckling is likely to be the criterion of ultimate strength.

In the general analysis the results of buckling formulas for ratios of thickness to unsupported width of one-fortieth and one-fiftieth were presented. Reference to Table 1 shows the $\frac{b}{t}$-ratios of the specimens tested to have varied from 32 to 48. The aforementioned results are quite applicable to these cases and clearly indicate that buckling is improbable in such cover-plates at stresses under the yield-point limit. The preceding discussion shows that stresses in execess of this limit are not realized under the most extreme conditions herein considered. In connection with this point it must be noted that the general buckling formulas become invalid as soon as the stresses pass the limit of proportionality, and furnish only roughly approximate values. For such cases the yield-point stress is usually considered the buckling stress. It is with regard to the latter point that the tests are significant. It might be reasoned that the wide thin cover is in an unstable condition when the stress reaches the yield point (Point B', Fig. 2(b)), and that local buckling of this cover should cause collapse of the entire section at a value slightly greater than the yield-point stress of the cover. However, in all cases except that of Column No. 3, despite the fact that a deformation twice that corresponding to the yield-point (Point B', Fig. 2(b)) stress was realized, there was no sign of buckling until the average stress over the entire section reached the yield point, and unlimited distortion became possible. In Column No. 3 where the $\frac{t}{b}$-ratio was $\frac{1}{48}$ (well below the limit permitted by most specifications), incipient buckling action was noticeable shortly after the extreme fiber had passed the proportional limit. However, the development of the buckle was so slow that the column as a whole maintained its integrity until, as in cases of other specimens, the average stress over the entire section attained a value slightly above the yield point.

It is believed that the reason for this action lies in the previously discussed fact that the distortion corresponding to entirely free plastic flow cannot take place in the cover, until the average stress is of sufficient intensity to cause the entire section to behave plastically. It is reasoned, therefore, that as soon as the cover reaches the yield point, and plastic flow takes place, the member assumes the deflected form with a greatly decreased resistance, the secondary stresses largely disappear, and the stress approaches uniform distribution across the section. Simultaneously, the distortion and direction of impending buckle of the cover-plate are controlled so as to permit the necessary deformations without actual buckling, thereby giving approximately the full yield-point stress as the ultimate load-carrying capacity of the section.

It has been noted that indications of buckling of the thin cover-plate in Column No. 3 were observed at an earlier stage of loading than for Columns Nos. 1 and 2, and that for an identical section in Column No. 4 simple stiffening devices were provided. The effectiveness of these stiffeners in holding the thin cover-plate in line in the region of high stress is clearly demonstrated. A comparison of Test 5, Column No. 3, with Test 7, Column No. 4 (the columns being identical except for the cover-plate stiffeners on the latter) shows that at the average unit stress causing a marked incipient buckling in Column No. 3, Column No. 4 showed no sign of such effects. While Test 8 (Column No. 4) showed a lower final value than Test 6 (Column No. 3), this was due to the fact that the former was not loaded to the point of complete collapse. At a load of 305 000 lb axial stress, however, the cover-plate was in better condition than that of Column No. 3 at the same load.

The results of the test indicated some serious defects in the particular stiffening device used. The sudden change in section at the end of the stiffener created a marked local field of stress concentration, the occurrence of which was indicated by the appearance of strain lines at a load well under the proportional limit of the column as a whole. It is clear that if such a stiffener is used, it should be extended farther toward the end of the column, or its section should be gradually tapered off to avoid such a marked change in cross-sectional area of the plate, since in the present case the unit stress in the plate adjoining the stiffener was practically equal to the maximum stress (stiffener and plate) at the center of the column. Further study and tests are required to determine the most effective form of stiffener, but the indications of this test are that a simple and inexpensive device of this type could readily be developed should it appear desirable to do so.

SUMMARY AND CONCLUSIONS

From the general analysis presented, the following significant features of secondary stress action may be summarized:

1.—Secondary stresses are limited and controlled by certain deflection quantities (see Equation (3)). For any particular loading condition, these deflections are (for primary unit stresses within the elastic limit) approximately proportional to the axial distortions of the truss members, considered as pin-connected, and when, for a given loading, these deflections have been attained, there is no further tendency for the stresses to increase.

2.—As long as both axial and bending stresses remain within the elastic limit and the transverse deflection is small, the behavior of a member under primary stress and secondary bending is closely analogous to a similar member under eccentric axial loading.

3.—If the maximum extreme fiber stresses pass the proportional limit, or if the member is of such type that the transverse deflection is large, the preceding analogy ceases to hold, since, in the case of secondary action, it is the deflection and not the moments that are proportional to the load. In particular, when the extreme fiber stresses reach the neighborhood of the yield point, a radical re-adjustment takes place, greatly relieving the flexural stresses.

4.—As a result of the re-adjustment in stress-strain relations, it may be inferred:

(*a*) That any tension member tends, as the load increases, to a condition of uniformity of stress over the cross-section, except for a local over-strain in a short section near each end.

(*b*) Compression members bent in single curvature may be seriously affected as regards $\frac{L}{r}$-failure if the transverse deflections due to secondary bending become large. This can only occur, however, in the case of large secondary moments and flexible members, a combination that is not ordinarily realizable. It was noted previously (see heading "Compression Member Bent in Single Curvature") that for values of $\frac{L}{r} \overset{=}{<} 70$, the effect of secondary action in inducing $\frac{L}{r}$-failure is small — well under that corresponding to a pin-ended column with normal "equivalent eccentricities" at the ends. In such a case the rigid joint action which gives rise to secondary stress acts as a brake on the long column deflection before the point of ultimate column strength is reached.

(*c*) For a column bent in double curvature, the secondary action, by forcing the curvature into two "waves", may actually have a beneficial effect as regards $\frac{L}{r}$-failure.

(*d*) For "stocky" columns $\left(\text{say, } \frac{L}{r} \overline{\overline{<}}\ 40\right)$, which are ordinarily the only members that develop high secondary stresses, failure is nearly always due to local over-strain. Until the average stress approaches the yield point, the transverse deflection is negligible, and column action in the ordinary sense cannot occur. For such columns the secondary stresses, whether resulting in single or double curvature (almost invariably the latter will be the case for high secondary stresses) will merely result in high stresses on the compressive face, which are rapidly relieved by plastic flow of the material as the yield point is approached.

5.—It might be expected that a combination of primary and secondary stresses beyond the proportional limit would adversely affect the stability against local buckling of the wide, thin cover-plates commonly used in the compression chords of bridges. An analysis of the problem indicates, however, that local buckling is unlikely to occur, in plates having a $\frac{t}{b}$-ratio consistent with the requirements of standard specifications, until the average stress over the column approaches the yield point of the material, which, in all compression members, marks the ultimate strength of the member.

The tests made primarily for the purpose of exhibiting the behavior of the box type of compression member with respect to local failure under primary stress and a high percentage of secondary stress, have been discussed rather fully in the previous pages. The test results may be summarized briefly, as follows:

6.—Re-distribution of stress beyond the proportional limit was found to take place in a manner closely agreeing with theoretical analysis.

7.—For combinations producing nominal values of extreme fiber stress as great as 55 000 lb per sq in. ($f_p = 35\,000$ and $f_s = 20\,000$ lb per sq in.), it was found: (*a*) That while strain lines began to appear in the cover-plates as the proportional limit was passed, no indications of local buckling appeared until the average stress over the section approached the yield point of the material, for plates with $\frac{t}{b} = \frac{1}{32}$ and $\frac{1}{42}$; but, (*b*) for plates with $\frac{t}{b} = \frac{1}{48}$, some evidence of incipient local wrinkling was noticed at a load somewhat less than the ultimate capacity of the column, although this had apparently no appreciable effect on that value.

8.—When stiffeners were applied to the cover-plates of Column No. 4 (see heading, "Cover-Plate Stiffeners"), the indications of incipient buckling noted in Column No. 3 (Summary Item 7(*b*)) were entirely absent.

Although the general analysis of the behavior of bridge members under combined primary and secondary action resulting in local stresses beyond the proportional limit is believed to apply without restriction, it is obviously impossible to draw valid general conclusions from the test results on four specimens. A much more comprehensive program of experimentation would have to be undertaken before a final pronouncement could be made. Subject to these limitations, the following significant conclusions are indicated:

(*a*) The ultimate practically utilizable strength of a tension member is not affected by any secondary stress action within reasonable practical limits.

(*b*) Compression members sufficiently flexible to develop $\frac{L}{r}$-failure before the yield point is reached, will usually exhibit too low a value for the secondary bending to reduce the ultimate carrying capacity of the member materially.

(*c*) The rigid type of built column, in which alone high secondary stresses are to be expected, almost invariably fails by local over-stress, usually at a point at which local buckling can readily take place. High secondary stresses have no effect in hastening such local failure, and, therefore, have no effect in reducing the actual ultimate strength of such compression members, providing the section proportions are governed by the limits of present standard specifications.

The results of the investigation do not justify the conclusion that secondary stresses are of no importance. The fundamental principle which has so largely governed structural design (that no fiber stresses should exceed the yield point of the material), is too firmly established and is supported by toc many sound reasons to be lightly ignored. Such a principle, however, cannot be applied blindly; it is of the utmost importance for the designer to know the consequence of overstressing any part of the structure. This may mean general failure, a limited, localized failure not endangering the structure as a whole, or merely undesirable local distortion and permanent set. The practical significance of this investigation lies in the fact that it indicates that overstressing due to secondary bending falls in the latter class. This is of vital importance in fixing the unit stresses and otherwise determining the margin of safety for cases in which high secondary stresses are involved.

The investigation does not cover certain important by-products of secondary bending as, for example, the effect on riveted and welded connections of alternating secondary moments. For certain types of joints, this effect may be quite important. Due to this and perhaps other effects, and the general desirability of avoiding large permanent set, it is highly desirable that the designer should know if and where high secondary stresses occur in a structure. Under certain conditions, he may deem it desirable to modify the design to reduce such stresses or to provide for them specially in the detail design. In any case, it is a matter of great practical designing significance to be assured that an unforeseen and unexpected overload, producing a combination of primary and secondary stress nominally far above the yield point of the material, will not endanger the safety of the member as long as the average stress over the section is maintained safely below the yield limit.

ACKNOWLEDGMENTS

All the experimental work was conducted in the Experimental Engineering Laboratory of the University of Minnesota, by aid of funds jointly furnished by the Graduate School, of which Guy Stanton Ford is Dean, and the Engineering Experiment Station, of which O. M. Leland, M. Am. Soc. C. E., is Director. Acknowledgment is also made of the co-operation of R. W. Robinson, Engineer of the Minneapolis Plant of the American Bridge Company, who furnished the test specimens at cost. The grateful thanks of the writers are also due to Professors C. A. Hughes and G. C. Priester for valuable criticisms and suggestions, freely given throughout the progress of the work; and to others who rendered valuable assistance during the conduct of the tests.

DISCUSSION

C. H. Sandberg,[21] Assoc. M. Am. Soc. C. E. (by letter).—Until recent years the analyses of the problems concerning secondary stresses and indeterminate stresses have been treated in a rather theoretical and academic manner. It is gratifying, therefore, to read a paper that discusses this problem of secondary stresses from a practical standpoint.

One point not emphasized by the authors is the advantage of knowing the effects of secondary stresses in determining the necessity for the replacement of old truss spans. Many of the old, riveted, railroad truss spans, for example, were fabricated with absolute disregard of eccentricity of connections. When the theoretical stresses are computed for the members of such trusses the extreme fiber stresses are often found to be at, or beyond, the yield point.

In addition to secondary stresses and those caused by seriously eccentric connections, some old truss spans carry the live load directly on either the top or the bottom chords. This causes extremely high combined stresses, in some cases; and yet the members are apparently carrying these theoretically excessive loads without any dangerous over-stress. Thus, engineers acquainted with old riveted truss spans can verify from actual experience, the conclusions advanced in this paper. Of course, it is agreed that secondary stresses and similar stress effects cannot be ignored indiscriminately.

It is of interest to note the beneficial effect of the stiffener bar that was welded to the cover-plate of Test Column No. 4. This method of stiffening could be applied, readily and cheaply, to compression members of existing old truss spans. It is hoped that some further investigations and experimental research will be made along these lines.

J. D. Gedo,[22] M. Am. Soc. C. E. (by letter).—The importance of this lucid paper is that it evaluates the effect of secondary stresses upon the ultimate strength and thus furnishes considerable information in regard to the fixing of rational unit stresses.

The only disturbing element in the exposition is that the secondary stresses sometimes are ascribed to the deflection of the truss (see under headings, "Synopsis", and "Analysis of Problem"), and sometimes to the gussets. If the first version were correct, one would conclude that there are no bending moments in the truss represented in Fig. 22, which is carved from a single piece of steel and in which every joint is supported.

[22] Senior Designer, Park Dept., City of New York, New York, N. Y.

L. E. GRINTER,[23] ASSOC. M. AM. SOC. C. E. (by letter).—The attempt of the authors to investigate the effect of secondary stresses upon the ultimate strengths of truss members deserves sincere applause. For a period of more than half a century the question of the importance of secondary stresses has been widely argued without any successful effort to reach even a compromise agreement. Practice ranges from the entire disregard of all secondary stresses to their full inclusion at standard working stresses. The designers of a few important structures have taken the intermediate path either of attempting to eliminate secondary stresses by the introduction of opposite erection stresses, or of taking the secondary stresses into consideration at increased working stresses.

There should be no disagreement with the authors' premise that secondary stresses should be disregarded if it can be shown that they do not hasten ultimate failure of the structure. However, there are many capable designers who will not agree with this statement because it seems in conflict with the conception of a factor of safety based upon the elastic limit of the material. After all, that is certain to be the major point of disagreement. The old conception of a factor of safety based upon the ultimate strength has been shown to be fallacious and has been replaced by a factor of safety (or better, a factor of ignorance) based upon the elastic limit. Now, it is suggested that the range of plasticity that exists barely above the elastic limit should be exploited to reduce the effect of the secondary stresses and add to the ultimate theoretical capacity of the structure.

The authors' suggestion will immediately bring up the subject of proper working stresses. It has been shown repeatedly that the maximum secondary stresses in an ordinary truss approach one-third the values of the corresponding primary stresses. Hence, a member designed at 18 000 lb per sq in. might actually be stressed to 24 000 lb per sq in. The range from 24 000 lb per sq in. to be the minimum elastic limit (between 30 000 and 35 000 lb per sq in.) has been considered sufficient to cover fabrication stresses, erection stresses, exceptional overload or unusual impact, and an allowance for reduction of area by corrosion. If the authors are prepared to suggest the entire neglect of secondary stresses in design, it would seem that this would permit an increase in the basic working stress of about 33 per cent. Probably most readers will be unwilling to agree to such an increase as being reasonable although they may feel that the authors have established their contention.

Although the authors point out that the "best standards of practice" require that provision for secondary stresses shall be made in design, it is well known that the great majority of designers have not had the necessary theoretical training to compute the values of the secondary stresses and, therefore, have depended upon the allowance in the working stress. Only with the introduction of the Cross method[24] and the writer's simplified method[25] has the designer had available a simple, rapid, and understandable method of secondary stress analysis. Based upon the assumption that the "best standards of practice" will continue to require the consideration of secondary stresses in design, there is reason to believe that "standard practice" will be developed to include the introduction of secondary stresses into bridge design at increased working stresses. In the past, the question as to whether secondary stresses should be introduced into a design has been largely academic, because of the lack of a convenient method of secondary stress analysis.

[23] Prof., Structural Eng., Agri. and Mech. Coll. of Texas, College Station, Tex.

[24] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), pp. 1–156.

[25] *Loc. cit.*, Vol. 99 (1934), pp. 610–669.

The entire argument of the paper is based upon the premise that secondary stresses increase in direct proportion to primary stresses until the yield point of the material is reached at one face of the member, after which an increase in primary stress is not accompanied by an increase in secondary stress. Two reasons are offered to explain this phenomenon. The first (with which the writer agrees) is that local plastic deformation will occur, which will redistribute the stress over the cross-section and maintain (temporarily) the extreme fiber stress at the yield point. The second (with which the writer disagrees), is made clear by the following quotation in reference to Fig. 3:

> "Since the angular rotations at the ends of a member can increase no more rapidly than the axial loads, it will be impossible even with high secondary stresses for the extreme fiber stress to exceed the yield-point value without the distortion increasing far beyond any value reasonably to be expected in a truss in service."

The title of this paper, however, indicates that the study relates to ultimate strength, and the deflections, the angular rotations, and the proportional secondary stresses will be several times as large at failure as those presupposed by the authors in the foregoing quotation.

Evidently, this entire matter needs to be clarified by an unqualified statement as to whether the structure is to be designed for working conditions, for an intermediate condition in which stresses will remain at the yield point during a considerable increase of load, or for those conditions existing at failure. If the authors select the intermediate condition unqualifiedly, they will approach more nearly to a justification of their hypothesis that secondary stresses are of little importance in design. However, they will then face the criticism that their structures designed with a standard factor of safety upon the yield point have far less reserve strength above the yield point than the designer has been accustomed to expect. This follows because joint rotations and secondary deformations increase more rapidly than the loads as soon as the direct stresses exceed the elastic limit of the material, and the authors have suggested no provision for secondary stresses in the design.

Considerable emphasis is given to the fact that stresses above the yield point are not unusual elsewhere in structural design. Of course they are not, although there is still a considerable group of engineers who object to plasticity as a basis for structural design. Nevertheless, when the authors declare that stress concentrations above the elastic limit probably exist around rivet holes, they should not forget that their suggestion of the entire neglect of secondaries assumes that this severely deformed material around the rivet holes will be able to continue to flow in order to reduce secondary stresses without developing incipient cracking. The reference to increased allowable bearing stresses on pins and rivets must be considered together with the obvious fact that the highly stressed material is restrained against flow by low stressed adjoining material. Professor Swain made this point clear by stating[26] that a cannon ball cannot possibly fail under hydraulic pressure.

An important factor not considered by the authors would seem to be the possibility of reversal upon accumulative plastic deformation. If reversal can be shown to be sufficiently important to over-stress, alternately, the opposite sides of a member, such accumulative distortion might be serious. Another obviously important consideration is the instantaneous stresses produced by live load impact and vibration. Since there would be no possibility of reducing such stresses by plastic flow, they could not be placed in the same category as the secondary stresses caused by dead load. Although it is difficult to visualize impact as producing deflection and joint rotation, there is reason to believe that the shock effect would increase both secondaries and primaries. In fact, since the secondary stresses do not support the load, it is easy to visualize the possibility that they might be doubled by the individual vibration of the member which could act as an instantaneous application.

In summarizing, the writer would like to express the opinion that this paper will be of great value in opening the entire field of secondary stresses and proper working stresses for discussion. However, he cannot at present agree that the paper justifies, entirely, its hypothesis that secondary stresses should be completely neglected. The probability of high secondaries near the ultimate load, the danger of over-dependence upon plastic deformation where other stress concentrations exist, the possibility of cumulative plastic deformation, and the impossibility of any reduction in secondary stresses caused by rapid advance of live load, or by impact and vibration, point to the danger that might be involved in a complete neglect of secondary stresses. Probably all could agree, however, that, if specifications are to be rewritten so as to make it obligatory to introduce secondary stresses into the design, a slightly increased basic working stress, further increased one-third as an allowance for secondary effects, is permissible.

This paper marks the authors as pioneers in pointing to the great possibilities that lie in the future for exploiting the advantages of steel as a plastic material.

L. T. Evans,[27] Assoc. M. Am. Soc. C. E. (by letter).—While the subject of secondary stresses has been popular with many writers, all papers prior to this one have left the impression that the analogous eccentric-load relation existed for all increments of load.

For some time the writer has felt that some relief must accrue to highly stressed parts of structural members when a large part of that stress was due to secondary moments. Actual structures substantiate this belief. Several years ago the writer was employed on the design of a large, steel, rigid-frame structure. The girders were trusses with web members that had secondary stresses as great as four times the primary stresses. Since these members were short and "stocky," with an indeterminate length (due to large gusset-plates), it was decided to design the section for the full primary, and one-half the calculated secondary, stress with the elastic limit as the working stress. After erection, the structure was encased in concrete and has been in daily service for several years with no signs of distress.

[26] "Structural Engineering—Strength of Materials", by George F. Swain, Past-President and Hon. M. Am. Soc. C. E., McGraw-Hill Book Co., N. Y., 1924, p. 551.

[27] Cons. Structural Engr., Long Beach, Calif.

This paper will be appreciated by engineers who have given secondary stresses considerable thought, but it is hoped that the careless reader will not get the impression that such stresses will "take care of themselves" and can be ignored.

F. E. Fahy,[28] Assoc. M. Am. Soc. C. E. (by letter).—The analysis presented in this paper defines clearly the effect of the relieving local deformations which have been said at times[29] to account, at least in part, for discrepancies (generally on the side of safety) between observed and computed stresses in riveted trusses. The writer has long felt that the calculation of secondary stresses by any of the usual methods involves too many rather arbitrary assumptions to be quantitatively accurate, and that the actual effect of secondary stresses on the members of a heavy riveted truss is closely akin, as the authors suggest, to the many cases of theoretically high localized stresses which are of little practical significance.

A rather interesting analogy might be drawn between the action of a riveted truss joint at which secondary moments cause deformations beyond the yield point, and that of a multiple-pin joint. Where a multiple-pin joint does not materially affect the static stability of the framework (at the intermediate support panel points of a continuous or cantilever truss, for instance) it can be used advantageously; it permits the connected members to rotate about their respective pins without incurring any flexural deformations except those due to pin friction. In such a case the stresses remain essentially axial. After the extreme fiber stresses in the connected members pass the yield point of the material, secondary stress action under rigid joint conditions will tend toward the same effect, except, as the authors indicate, in the case of slender compression members bent in single curvature. The points of yielding might be considered as approaching pin-end conditions, about which the members involved "rock" to a final state of static equilibrium.

The foregoing analogy will not apply beyond the first application of load because of strain hardening, but it is suggested as a convenient method of visualizing the action of a truss in which flexural overstress occurs due to secondary bending. (As a matter of convenience the writer will use the term, "overstress," to mean stress beyond the elastic range.) In many cases, incidentally, it is the first loading stage that is final and most important; heavy building trusses, perhaps the worst offenders in the matter of high secondary stresses, are essentially dead load structures, and after the first application of full load has imparted to them a certain deformed condition, will hold that condition under the subsequent steady loads to which they are subjected. The truss outlined in Fig. 23 (*a*) can assume the position shown in Fig. 23 (*b*), in which deformations have been idealized and exaggerated for the sake of clearness; and, under the small deformations which actually occur, it can hold that position without harm. It may be noted, also, that the inherent instability of a multiple-pin joint does not appear in an overstressed rigid joint because of the fact that the overstressed members can always offer flexural resistances (until, of course, failure is imminent) even after the extreme fiber stresses have passed the yield point.

E., Vol. LXXXII (1918), p. 1071; and "Investigation of Secondary Stresses in the Kenova Bridge," by G. A. Maney and J. I. Parcel, Members, Am. Soc. C. E., University of Minnesota, *Studies in Engineering*, *No. 4*, p. 3.

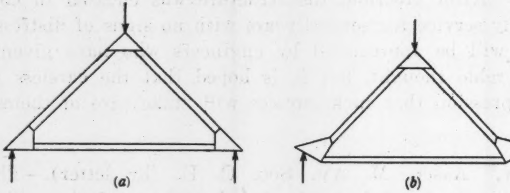

FIG. 23.

It might be suggested that in small bridges, especially railway bridges, which are essentially "live load structures," fatigue might play a fairly important part in causing failure if the combined effect of dead load, live load, and impact stresses runs as high as the yield point of the material. Current practice properly tends to neglect fatigue as a serious consideration in discussing the utilizable strength of such structures. In the first place, the number of full-load applications which the ordinary bridge receives during its normal life span is so small as to preclude the necessity for considering fatigue either in design or review. Assume, for the sake of argument, however, that this is not the case. All the evidence with which the writer is familiar at the present time seems to indicate that for most ferrous metals the endurance limit for a stress ranging from zero to a maximum value of one sign only is well above the static yield point of the material. The Goodman value is 1.5 times the endurance limit for completely reversed stress, which endurance limit, for the ferrous metals, seems to approach roughly a value equal to one-half the ultimate strength.[30] (In general, for the types of steels commonly used in bridges the endurance limits for completely reversed stress appear to be somewhat less than the yield points, but not enough less than the usual specified minimum yield points[31] to invalidate the comments which follow.) For the ordinary carbon steel commonly used in short-span and medium-span bridges the yield point is also, roughly, equal to one-half the ultimate strength. As the authors have indicated, stresses in bridge members, even with low length-depth ratios, will scarcely exceed the yield point, which means that such stresses can never reach the endurance limit for a range ratio of zero. Furthermore, bridge members which are short enough to be under high secondary moments will almost always be under some dead load stress, in which case the stress range decreases and the endurance limit increases. An exception might be the case of comparatively heavy web members in the center panel or panels of a shallow deck truss. In these members, stress reversals due to secondary bending are quite likely to occur, and reversed primary stresses actually do occur. It would be a rare case indeed in which the resultant primary and secondary stresses in such members in a well-designed structure, would approach anything like the yield point or the endurance limit of the material. The writer simply introduces the subject of fatigue, and the foregoing discussion, as further substantiating the authors' conclusions that, in well-designed structures, overstressing due to secondary bending generally means either a "limited, localized failure not endangering the structure as a whole, or merely undesirable local distortion and permanent set."

---

[30] "The Fatigue of Metals", by Moore and Kommers, pp. 160–165.

[31] *Loc. cit.*, pp. 128–146; also, A. S. T. M. Standards.

The writer does not mean to imply that consideration of secondary stresses should be omitted entirely from the design process. No conditions under which stresses reach the yield point of the material can be considered as other than most undesirable and to be avoided if at all practicable. As far as the members themselves are concerned, however, the writer concurs with the authors in their conclusion that the presence of secondary bending stresses even as high as the yield point are not necessarily damaging; nor are they to be considered as rendering the structure unsafe or poorly designed.

A brief discussion of the effects of secondary bending on the joints of a structure seems pertinent, especially in considering secondary stresses due to live load. The presence of secondary moments at a truss joint means that the connection between member and gusset-plate ceases to be a direct tension or compression joint, but must resist flexure as well. Since the intensity of this flexure varies considerably, in the average structure, between the dead load and full live load plus impact conditions, there may be considerable danger of loosening the rivets and generally overstressing the entire group, in a riveted joint, or of causing progressive fracture of a weld.

Consider a tension member made up of two 15-in. 55-lb. channels laced or battened together, each channel being riveted to the gusset-plate by means of thirty $\frac{7}{8}$-in. rivets, as in Fig. 24. Assume that the full dead load, live load, and impact stress in the member is 16 000 lb per sq in. of net section, and that the minimum live load stress is zero. (The writer has made this assumption partly for the sake of simplicity and partly because of the fact that under most current specifications members and connections which are sub-

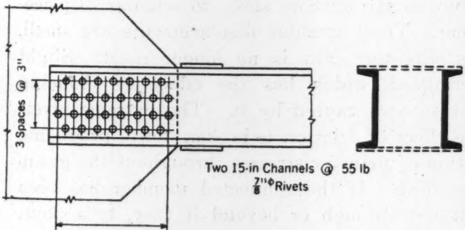

FIG. 24.

ject to reversals of primary stress are quite conservatively designed. Furthermore, such members are usually relatively slender and not likely to be subjected to high secondary stresses. Reversals of secondary bending may heighten the effects noted herein, but the writer has made no attempt to make the examples which follow especially severe, except in so far as secondary bending causes yield-point stresses.)

Basing the allowance for rivet holes on the 1923 specifications of the American Railway Engineering Association, this gives a total primary stress due to dead load, live load, and impact of 431 000 lb. The total primary stress per rivet is then $\frac{431\,000}{60} = 7\,180$ lb. The gross area of the member is 32.22 sq in., giving a primary stress of 13 400 lb per sq in. on the gross section. The section modulus of the member, based on gross section, is 114.4 in.^{3} Assuming a yield point of 32 000 lb per sq in., the secondary bending moment required to produce yielding in the extreme fiber will be $(32\,000 - 13\,400) \times 114.4 = 2\,130\,000$ in.-lb. The moment of inertia of the rivet group (Σd^2) is 3 160 in.,^{4} and the distance from the centroid of the group to the extreme rivet is 10.6 in. Then the total stress in the extreme rivet due to the secondary moment which will produce yielding in the member is $\frac{2\,130\,000 \times 10.6}{3\,160} = 7\,130$ lb. Combining this with the primary stress of 7 180 lb and neglecting the probably small transverse shear which is caused by reversed bending or unequal end moments, gives a resultant total stress of 10 900 lb on the extreme rivet, or 18 100 lb per sq in. in single shear. This is approximately the shearing yield strength of the rivet. If 25% of the total stress is due to dead load, the stress in two of the extreme rivets of the group will vary from 4 500 lb per sq in. to 18 100 lb per sq in. If the rivet has slipped at the first full-load application (as it probably has), it would appear that a relatively small number of live load applications would suffice to loosen it beyond any useful resistance, and thus produce progressive failure of the joint—especially when the highly non-uniform distribution of primary stress among the rivets comprising the group is considered.

Here again, however, the nature of secondary stress action must be remembered. It is essentially due, as the authors state, to angular displacements of the ends of the member. These angular displacements are small, and when the rivets themselves slip, the joint is no longer rigid. Slight rotation of the member is permitted, which has the effect of reducing secondary bending and the rivet stresses caused by it. The extreme rivets will slip at low stresses, once the effect of friction is broken down, producing at once a more uniform distribution of primary stresses throughout the group and a reduction in secondary bending. If the connected member has been deformed to the yield point, but not through or beyond it (say, to a point slightly to the right of Point *B*, Fig. 2(*a*)), the effect on the rivets may not be damaging, although the sharp rotation occurring at the overstressed section will introduce some eccentricity of primary stress. If it has not been so stressed, slip will not reduce the loosening effect of rotation and counterrotation of the joint. Field and laboratory investigation of the effect of variable bending on groups of rivets in shear would be of value in connection with the subject of secondary stress effects.

Rivet slip may play an appreciable part in reducing secondary bending, which accounts to some extent for discrepancies between observed and calculated stresses. The relieving effect of rivet slip is not to be found in welded joints, although it has a counterpart in the plastic flow which occurs at the ends of such joints even under low loads. Due to the fact that welds are usually located along the edges of the member, the moment of resistance of a welded joint will be relatively higher than in a web-riveted joint, on the usual design assumption of uniform stress distribution through the length of the joint. Even so, however, the stresses in a welded joint at which the connected members are stressed to the yield point by secondary bending, will be high.

The damaging effect of high secondary stresses will likely be most severe on the joints at the ends of non-continuous members, such as the web members, end posts, and end-panel chords of the ordinary types of bridge and building trusses, and on splices in chord members, where such splices are near the panel points. This will be especially true for members in which the ratio of dead load stress to total dead load plus live load plus impact stress is low or negative. Severe joint stresses are not likely to occur at panel points at which the chord is continuous, except in the web-member connections. In Fig. 25(*a*), for example, $M_1 = M_2 + M_3 + M_4$, and if the chord is continuous only $M_3 + M_4$ must be resisted by the rivets between the chord and the gusset-plates. These rivets are usually considerably in excess of those required for primary stress transmission, and, due to the length of the joint, the group has a high moment of resistance against torsional loads.

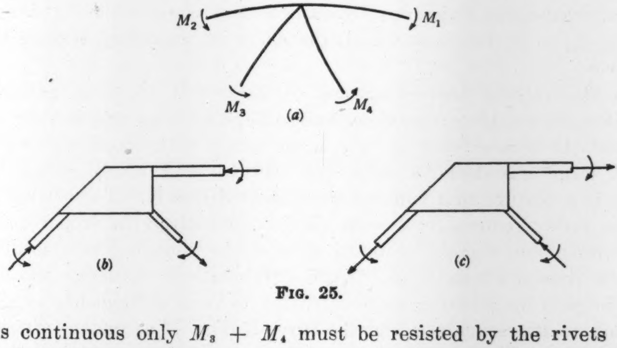

FIG. 25.

Another point which may be worth mentioning is the possible effect of high joint moments in causing severe stresses in the gusset-plates. If the stresses in a gusset-plate due to joint moments are opposite in sign to those due to primary stresses in the members the net effect will be a relief and lowering of the gusset-plate stresses. Such would be the case for the joint of Fig. 25(*b*), under the stresses and moments there shown. If, however, the primary stresses act as shown in Fig. 25(*c*), the secondary stresses add directly to the primary stresses in the gusset-plate. If the result is a tensile stress at a rolled edge of the plate equal to the yield point of the material no serious damage will result, either statically or from fatigue. At a sheared edge there may be some danger of progression of an incipient crack. If the resulting stress at the edge of the plate is compressive and equal to the yield point of the material, buckling may occur unless the unsupported edge of the plate is very short or unless it is stiffened by angles or a diaphragm connecting the usual pair of plates to each other. In the case of fairly large plates under compressive stress along a long unsupported edge, diaphragms or stiffener angles provide an easy and effective means of insuring, to a certain extent, against failure of the plate by buckling. In any design where high secondary stresses are likely to occur gusset-plates stresses should receive some consideration.

LAMOTTE GROVER,[32] ASSOC. M. AM. SOC. C. E. (by letter).—The practical application of the results of secondary stress analysis to the design of bridge members is discussed in this paper. This subject is most timely in view of the recent tendency toward the use of more comprehensive design methods in order to effect the most favorable distribution of material.

The increased demand for comparatively shallow deck truss construction resulting from higher standards in grade and alignment for both highway and railway structures, together with the trend away from movable spans to the use of fixed spans which require shallow deck construction in many cases, results in types of design in which the effect of secondary stresses is quite appreciable.

With the rapidly increasing use of structural welding, advantage is being taken of the better economy and reliability thus afforded for making rigid joints in which behavior can be predicted with more certainty. The effect of large gusset-plates upon the stiffness and stress distribution in members is a feature that can not be evaluated closely. These large gusset-plates are either reduced in size or eliminated entirely in properly designed welded connections, thereby reducing some of the annoying uncertainties that exist with riveted construction. Such developments challenge the designer to keep in pace by devoting more attention to such refinements as statically indeterminate stress analysis and the investigation of secondary stresses, and they also make it possible for the interpretation of such analysis to be evaluated more accurately and, therefore, better justified.

Certain other problems of the structural engineer, such as residual stresses caused either by rolling steel shapes or by welding, are inherently self-limiting and these stresses will be better understood as a result of the studies described in this paper. One of the ways in which structural welding will have an influence upon behavior under secondary stress is that welded cover-plates will be virtually fixed along their edges. This will contribute further toward minimizing the tendency for relatively thin plates to fail locally by buckling. Several limitations of the study have been acknowledged by the authors and these might be extended to include a number of others that would indicate the need for further and broader studies in this field.

---

[32] Bridge Engr., Dept. of Design, State Highway Comm., Topeka, Kans.

Further experiments should be made to determine the effect of heavy gusset-plates and the stress concentrations that they cause at the ends of members in double curvature, where the secondary stresses are most serious. Studies might well be made to demonstrate the effect of elaborate provisions which have been made during the construction of some of the larger bridges for the purpose of relieving secondary stresses.

Another condition that would be worthy of investigation is that of an occasional severe strain accompanied by plastic flow, with intermittent strains of lesser magnitude and of a frequency that approaches that which is recognized to be dangerous from the standpoint of "fatigue" failure. It is quite possible to obtain a sufficient number of repeated or alternating stresses to cause apprehension in this regard, if the life and service of modern bridge structures are to be as great as is estimated by many.

The authors have mentioned the possibility of unfavorable effect upon riveted or welded joints due to repeated or alternating stresses, but it should be emphasized that the effect of such stresses might be very severe upon the members themselves, especially in those connected with heavy gusset-plates and bent into double curvature as a result of secondary stresses; and likewise the effect of suddenly applied loads in causing combined stresses of serious magnitude before the metal has had time to creep and permit the adjustment of the stresses over the section by plastic flow. These remarks are especially pertinent in the case of smaller, lighter bridges.

It should also be stressed that the authors' "Summary and Conclusions" pertain exclusively to structures for which an occasional severe overload may be anticipated. They pertain to the stresses that would be caused by such an occasional load as might be expected in the case of a highway structure. Perhaps the results of the studies and experiments are less pertinent in the case of railroad bridges where the loads are subject to more careful control and are of at least daily occurrence.

No explanation is given as to the reason for the inward "dishing" of cover-plates as a result of local buckling, except the general tendency of the bending of a compression member as a whole. It might be considered questionable whether this tendency is decided enough to justify relying upon it, especially if other influences such as rust due to neglect in maintenance, tend to cause outward "dishing."

A. A. Eremin,[33] Assoc. M. Am. Soc. C. E. (by letter).—The analysis of secondary stresses at the yield point in a steel truss has considerable economic importance. The authors state that the ultimate strength of a steel truss is not affected by the secondary stresses at the yield point. This is true in respect to a truss in which the number of members, n, and number of joints, N, satisfy the equation,[34]

---

[33] Associate Bridge Designing Engr., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

$$n = 2N - 3 \qquad (18)$$

If n is less than $2N - 3$, the fiber stresses at the yield point in the joints will permit excessive displacements and evidently will influence the ultimate strength of the truss. This may occur in a Vierendeel truss in which the secondary stresses at the yield point will affect the ultimate strength of the truss.

If n is greater than $2N - 3$, the secondary fiber stresses at joints as well as the axial stresses in some members of a steel truss, may reach the yield point without materially affecting the ultimate strength of the truss.

The secondary stresses at the yield point may also influence the distribution of the axial stresses in the truss members when the stiffness of the members or the eccentricity of the joints is considered in computing the axial stresses.[35] A method of computing axial stresses, taking the stiffness of the members into consideration, has been presented by Charles A. Ellis, M. Am. Soc. C. E.

The authors are to be congratulated for their valuable contribution to the theory and practice of diagnosing the stresses at the yield point.

JOHN I. PARCEL,[36] M. AM. SOC. C. E., AND ELDRED B. MURER,[37] JUN. AM. SOC. C. E. (by letter).—The discussions submitted have raised a number of additional points of interest not mentioned in the paper or at most touched upon very lightly, and they have also called attention to certain apparent obscurities of statement. The writers are much gratified that, for the most part, the discussers appear to agree with the main conclusions of the paper.

Mr. Sandberg makes a very good point with reference to the importance of knowing the effect of high secondaries upon the ultimate strength of members in the case of determining the strength of old structures still in service, where it is proper to use a much lower margin of safety than would be the case for a new structure. He mentions the common occurrence of eccentric connections in such structures. It is important to note that secondary stresses arising from this cause are of a character quite different from those contemplated in the paper, as will be further noted in the consideration of Mr. Eremin's discussion.

The point of Mr. Gedo's criticism is not quite clear. He notes as a "disturbing element" that secondary stresses "sometimes are ascribed to the deflection of the truss * * * and sometimes to the gussets". This certainly was not the writers' intention. Secondary stresses as herein considered, of course, arise from a combination of the deflection of the structure and the stiffness of the joints as stated in the first paragraph under the heading, "Analysis of Problem". The frame-work shown by Mr. Gedo in Fig. 22, if the supports are assumed as rigid, would exhibit neither primary nor secondary stresses.

[35] "Williot Equations for Statically Indeterminate Structures in Combination with Moment Equations in Terms of Angular Displacement," by Charles A. Ellis, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 580.

[36] Cons. Engr. (Sverdrup & Parcel), St. Louis, Mo.

[37] Wayland, Mo.

The first three paragraphs of Professor Grinter's very able discussion contain a particularly clear and forceful statement of the salient points involved in estimating the importance of secondary stress upon ultimate strength. Professor Grinter disagrees with the statement in the paper that the joint rotations upon which the secondary stresses are conditioned increase in direct proportion to the load. He regards this as inconsistent with the title of the paper, which would indicate that the conditions to be considered are those in force when the structure is stressed to its ultimate limit, in which case he states that the displacements would be several times as great as those computed on the basis of elastic behavior.

It is believed that this criticism rests upon a misconception. It is definitely stated in the paper that the effective ultimate strength of a tension member is marked by the yield point of the material, and that ordinarily a compression member will fail at a point slightly above (and, on occasion, at a point slightly below) this stress. The most important conclusion of the paper is that secondary stresses, even when they result in local stress combinations nominally in excess of the yield limit, do not apparently hasten the development of an average stress over the entire section equal to the yield-point stress. So long as the average axial stress remains within the elastic limit, the joint rotations cannot increase faster than the loads, since they are direct functions of the changes of length of the truss members, and the latter, so long as Hooke's law prevails, are directly proportional to the loads. It was not the writers' intention to consider the distortions arising after the average primary unit stresses had reached the yield point.

Professor Grinter apparently feels that one should not place too much dependence upon the analogy between local over-stress due to secondary bending and that due to a number of other causes mentioned in the paper. With this opinion the writers are in entire agreement as should be clear from the statement made in next to the final paragraph of the paper. The point to be made was merely that standard practice at present permits certain violations of the general rule that all stresses should be kept within the yield-point limit, and that the mere fact that secondary stresses exceed this limit does not, without further consideration, establish them as dangerous.

The suggestion that due consideration should be given to the fact that high secondary bending places added strain on the material around rivet holes, which is already strained considerably beyond the surrounding material, is worthy of special consideration. The importance of this effect is considered in some detail in Professor Fahy's discussion. Undoubtedly, further experimental work upon the entire problem of the detailed behavior of riveted and welded joints subjected to a combination of high primary and secondary stresses is much to be desired.

Professor Grinter raises several interesting questions regarding reversal of stress, repetitive stresses, and impact, although the writers are inclined to feel that this interest is largely academic. As regards reversal and repeated stress, the following should be noted:

(1) In any ordinary bridge truss, the only members in which a marked reversal of both primary and secondary stresses takes place are the comparatively slender flexible web members near the center (of a simple truss) for which the secondary stresses are very small.

(2) Relatively stocky members which normally exhibit high secondary stresses—chords, end posts, short web members in end panels—ordinarily do not reverse either primary or secondary stress in a truss with simple webbing such as is commonly used for bridge trusses of spans up to about 300 ft. For longer spans, in which sub-paneling is used, some of this group of members may show a very large reversal[38] in live load secondary bending (although not, of course, in primary stress) when the secondaries are computed in the conventional manner. When a more accurate analysis is made, taking into account the induced distortions,[39] the secondary moments are found to be greatly reduced, and, when dead load effect is considered, they will almost never be sufficient to reverse the total extreme fiber stress appreciably.

(3) Structural steel with a yield-point value of 35 000 lb per sq in., may be expected to show a safe "endurance range" of from, say, − 20 000 lb per sq in. to + 35 000 lb per sq in.; or, when no reversal takes place, from 0 to 45 000 lb per sq in. It is believed that the present study shows conclusively that in no case can an extreme fiber stress be developed to exceed the yield-point value (35 000 lb per sq in. in this case) until the primary stress approaches this limit; that is, until failure is impending, regardless of secondary bending. It is also believed that only a "freak" truss will ever show a reversal of total extreme fiber stress ranging from − 20 000 lb per sq in. to + 35 000 lb per sq in. The extraordinary case where such action may take place, of course, will require special treatment.

Professor Grinter argues that impact stresses must be treated separately, since they may be practically instantaneous in character, allowing no time for relief to develop through plastic flow. This is a very important point and requires some further development of the conception of "relief".

If a designer is working to specifications requiring a minimum yield point of, say, 33 000 lb per sq in., and if he finds that in a certain compression member, for example, the computed maximum primary unit stress is 20 000 lb per sq in. and the corresponding secondary stress on the extreme fiber is 18 000 lb per sq in., he will naturally infer that his material at the face of the member is stressed 5 000 lb per sq in. beyond the yield point and, therefore, in danger of collapse due to local buckling. A principal conclusion of the paper was that, due to relief from plastic action, a stress greater than 33 000 lb per sq in. in such a case cannot possibly develop under any degree of secondary bending practically realizable. Remembering that in secondary stress action it is distortions and not stresses that are fixed, it is pertinent to ask: What will be the effect on the material if a given deformation is imposed on a member so rapidly that the material has no time to flow? It may be presumed that in this case a much higher stress will develop, but since it is strain and not stress which, repeatedly applied, tends to break down the material, it is not clear that, as long as the strain is the same, whether imposed instantaneously or gradually, there is any serious effect from the added stress required in the former case. So far as is known there are no experimental data bearing directly on this point.

---

[38] "Secondary Stresses in the Kenova Bridge", by G. A. Maney and J. I. Parcel, Members, Am. Soc. C. E., Univ. of Minnesota, *Studies in Engineering, No. 4*, p. 29.

[39] *Loc. cit.*, p. 47 *et seq.*

Professor Grinter states that "it is difficult to visualize impact as producing deflection and joint rotation". It would appear that since such displacements are the direct result of the axial deformations of truss members, as previously noted, they should be as clear and definite as distortions arising from other sources. Any calculation of secondary stresses should always include impact effects as well as those due to static live load, and recent researches appear to indicate that the allowance for impact required in standard railroad bridge specifications is probably considerably greater than is ever actually realized.

Professor Grinter refers to "the authors' suggestion of the entire neglect of secondaries". No such suggestion was made; on the contrary, the writers specifically state "the results of the investigation do not justify the conclusion that secondary stresses are of no importance". The exceptional cases cited by Professor Grinter as possibilities are among the reasons for this conclusion.

He states further that "in the past the question as to whether secondary stresses should be introduced into a design has been largely academic, because of the lack of a convenient method of secondary stress analysis" and that, "only with the introduction of the Cross method and the writer's simplified method has the designer had available a simple, rapid and understandable method of secondary stress analysis". With this statement, the writers are in complete disagreement. They have the greatest respect for the brilliant method of analysis introduced by Professor Cross and extended by Professor Grinter, and they recognize, of course, that there is always a wide difference of opinion among individuals as to the convenience and effectiveness of different analytical methods. So far as secondary stress computation is concerned, however, an extended experience has convinced them that the slope-deflection method, when the equations are solved by the method of successive substitutions, is a more rapid and convenient method than moment distribution. This method of solving slope-deflection equations has been in use for at least a quarter of a century.

Mr. Evans agrees with the main conclusions of the paper and notes that he has for some time held similar views. In this connection the writers would like to emphasize the statement made in the paper that the idea of large stress relief in the case of high nominal secondaries is by no means new and has been proposed by a number of authorities here and abroad during the past twenty years.

Mr. Evans cites a most interesting case arising in his practice a number of years ago in which a design solution was evolved, which embodied essentially the conclusions of this paper, and the subsequent results of which afford a confirmation of the soundness of the design.

The writers consider Professor Fahy's discussion a most important contribution to the subject. It is so thorough and clearly stated as to offer little room for comment. They have found his detailed study of rivet stresses and comments thereon especially illuminating. As regards the last point made in his discussion—the effect upon gusset-plates of a combination of high secondary and primary stresses—they feel that some further experimental investigation is needed before any final conclusions can be drawn. Until such information is available, they are inclined to agree with him that in all doubtful cases the edges of gusset-plates should be reinforced.

Mr. Grover raises a number of interesting questions, particularly as regards the effect of secondaries on riveted and welded connections, some of which are partly answered in Professor Fahy's discussion. His questions on the subject of fatigue have been answered in the comment on Professor Grinter's discussion. He refers particularly to the stress concentration arising at the edge of gusset-plates as a point which should receive special consideration in further investigations. If the writers understand correctly what he has in mind, they are inclined to feel that there is no essential difference in the stresses to which he refers and any other secondary stress of equal intensity occurring in the body of a member.

The inward dishing of the cover-plate to which Mr. Grover refers was not offered as a phenomenon which could be depended upon invariably, but rather as one that served to explain in part certain experimental data obtained. Of course, serious rusting or injury causing a marked incipient outward dish in the member would tend to offset the apparent natural tendency of the plate to bend inward.

Mr. Eremin raises two important points which perhaps should have been emphasized more in the paper. It is true that the term, "secondary stress", has been used rather loosely in the literature of structural engineering and is sometimes thought of as any bending stress developing at the ends of a member in a framework with rigid joints. This, of course, is not the type of stress with which the present investigation deals. It is noted in the "Introduction" that secondary stresses are not required to maintain the equilibrium of the structure, which clearly excludes such types as the Vierendeel truss; such structures are unstable without the resistance offered by the rigid joints. Under the heading, "Analysis of Problem", it is stated that,

> "Even when the secondary unit stress is a high percentage of the primary, the secondary moments offer no appreciable assistance in carrying the loads, and the members are always designed on the basis of full hinge action at the ends."

Perhaps this statement is too sweeping a generalization, although the writers know of no case in which a bridge or building truss (using the term, truss, to mean a framework with $m \gtreqless 2n - 3$) has been designed so as to include the secondary bending in the load-carrying capacity of the truss.

If a structure were so designed the bending moments in the members would become primary effects and as such are outside the scope of the present treatment.

For the most part, the same remarks apply to so-called secondary stresses arising from joint eccentricity. Such stresses are necessary to maintain the stability of the structure; in general, they will increase substantially in proportion to the primary stresses and, since a certain definite applied moment is to be balanced, no relief will result from local stressing beyond the yield point.

THE SPRINGWELLS FILTRATION PLANT, DETROIT, MICHIGAN

By EUGENE A. HARDIN[1], M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. F. H. STEPHENSON, ROBERT SPURR WESTON, AND EUGENE A. HARDIN

SYNOPSIS

The design and construction of a filtration plant and filtered water reservoir at Springwells Station is described in this paper. These units form a part of the additional works constructed during 1929-1932 for the Board of Water Supply of the Metropolitan Area of Detroit, Mich. The filtration plant is of the rapid sand, gravity type, having an ultimate capacity of 300 000 000 gal daily. The reservoir is in two sections each of which has a capacity of 20 000 000 gal, with provision for a third section to be added later. The general basis of design, the data pertaining to the various parts of the plant, the hydraulics of plant flow, the construction program, and the tabulation of both construction costs and engineering costs are outlined herein.

The water supply for the City of Detroit is the largest to be completely filtered by rapid sand filtration, and includes the two largest rapid sand filtration plants in the world—the Water-Works Park Filtration Plant, having a maximum daily capacity of 360 000 000 gal, and the Springwells Filtration Plant, having a maximum daily capacity of 300 000 000 gal (capacities based on a filtration rate of 180 000 000 gal daily per acre).

HISTORY OF WATER TREATMENT AT DETROIT, MICHIGAN

The City of Detroit has taken its water supply from the Detroit River for more than 100 years. Although privately owned and operated for the first eight years of their existence, the water system and supply works have been owned by the municipality since 1836. Since that time, from a small city of

6 900 inhabitants, the district served has increased in population to more than 2 000 000 and in area to more than 100 sq miles, extending about 10 miles along the river and about 10 miles inland from the river. Improvements for increasing the quantity of the supply, and its distribution, were the main considerations, except in the location of intakes, until, in 1912, when purification of the supply was first considered and permanent provision was made for chlorination. The quality of the water in the Detroit River at the intake built in 1905 (named 1905 Intake) has been comparatively good, but with increasing pollution and the growing consciousness of the consumers of the value and need of improvement in the quality of the water, the desire for a purer and more palatable supply increased until, in 1917, an experimental filtration plant with a capacity of 200 000 gal per day was constructed and operated for more than a year, establishing the feasibility of filtering and developing popular approval by dispensing filtered water to those who came for it. One year of operation (from October 1, 1917, to September 30, 1918) was used as the basis of a report by the late R. Winthrop Pratt, M. Am. Soc. C. E., dated March 1, 1919, outlining the general design of a filtration plant, to treat the entire then existing supply. In 1921, contracts were let for filtration works at Water-Works Park Station (see Fig. 1) and the filtration plant was completed and put in service on December 22, 1923.

While it improved the quality of the water greatly, the filtration plant at Water-Works Park did not add to the quantity. Due to the rapid increase in size of the city in both population and area, it was evident that a far-sighted and comprehensive plan of additional supply for the Detroit Metropolitan Area was necessary immediately. Accordingly, a Commission of Consulting Engineers, composed of Messrs. George H. Fenkell, W. C. Hoad, Clarence W. Hubbell, Theodore A. Leisen, and the late Gardner S. Williams, Members, Am. Soc. C. E., was appointed, and reported jointly on January 5, 1924. This Commission recommended an extensive program, involving the construction of additional supply works, beginning immediately with (*a*) the building of a new intake in the river; (*b*) a raw-water tunnel from intakes to the west side of the city; (*c*) a complete new supply station at the site selected on the west side; (*d*) additional distribution mains; and (*e*) future construction of a third complete supply station at a site to be selected in the northeastern part of the city. Item (*c*) included recommendations for a low-lift pumping plant, a filtration plant, a filtered water reservoir, and a distribution pumping plant.

GENERAL DESCRIPTION OF FLOW

The new system provides for the distribution of additional water to the Metropolitan Area of Detroit from three separate stations, each having a filtration plant and the necessary pumping plants (see Fig. 1): (1) The old Water-Works Park Station on East Jefferson Avenue; (2) the Springwells Station on West Warren Avenue; and (3) a future Northeast Station (see Fig. 1). The water is taken from a new, lagoon type, intake built in the Detroit River just northeast of the up-stream end of Belle Isle and not far from the 1905 Intake crib, which will remain in service as an auxiliary intake, and will be

carried through a system of gravity tunnels to the old station and across the city to the new stations. The intake, the Springwells Station, and the raw-water tunnel connections to Water-Works Park Station and Springwells Station are part of the present project. Northeast Station and the branch tunnel to it will be built at a future date.

The water to Springwells Station flows from the intake through 3 568 ft of concrete-lined tunnel, 15.5 ft in diameter, built in rock under the river, to a riser well and screen chamber on the shore at Water-Works Park; thence through 10 633 ft of concrete tunnel, 14.0 ft in diameter, in clay, north to the intersection of Pennsylvania and Forest Avenues; thence west through 44 705 ft of concrete tunnel, 12.0 ft in diameter, in clay, to the Springwells Station site, where it turns and enters the suction well of the raw-water (low-lift) pumping plant.

At this point the pumps elevate the raw water into the mixing chamber of the filtration plant through two 10 by 8-ft (or equivalent section) concrete conduits running behind the pumping plant and under the generator plant floor. The flow through the filtration plant is shown in Fig. 2. (The superstructures of the plant are not shown.) Just before entering the mixing chamber the water is metered through Venturi tubes cast in the concrete conduits. Coagulants or chlorine may be applied to the raw water at the entrance to the low-lift plant, at the entrance or exit of the raw-water meters, or at the entrance to the mixing chamber. Thorough and rapid dispersion of the chemicals through the water is accomplished by the turbulence in the pumps, meters, or entrance gates, as the case may be. In the mixing chamber the water is stirred by mechanical agitators and brick baffles.

The mixing chamber discharges into a conduit running the full width of the four settling basins, from which conduit the water may rise at two junction and gate wells which admit the water into the distributing channels of each basin. Entrance to the basins is through vertical slots spaced to give uniform distribution. After passing through these basins at settling velocities the clarified water is decanted from the surface by weirs, and flows into the filter building at two points through main conduits. At the filter operating galleries these conduits branch into the filter influent mains from which the inlets are connected to the sixty-eight rapid sand-filter units. The water flows on to the filter sand beds from the inlets and passes through 20 in. of sand and 18 in. of gravel to the perforated-pipe grid collector system below.

The filtered water that is collected is discharged through automatic rate-of-flow controllers into the main filtered-water conduits in each of the two pipe galleries between the four rows of filters. The two filtered-water conduits discharge into a weir chamber at their eastern ends where the water level is controlled to maintain submergence of the filter-effluent piping as well as the high suction level on the distribution pumps when operated according to the shunt system, described subsequently. From the weir chamber the water may flow either directly to the pumping plant or into the filtered-water reservoir, as flow conditions demand.

Circulation in the filtered-water reservoir is induced by a center baffle-wall in each section and inlets and outlets controlled by flap check-gates. Water

is drawn from the reservoir through conduits entering the opposite end of the pumping plant to that connected directly to the weir chamber. The distribution pumps discharge through steel mains connected to each of two service districts (a high-pressure area and an intermediate pressure area, see Fig. 1), which are served jointly by the Water-Works Park Station and the Springwells Station. The detailed description which follows covers only the design and construction of the filtration plant and reservoir at Springwells Station.

EXPERIMENTAL WORK AND STUDIES PRELIMINARY TO DESIGN

Experimental Filter Plant.—In the summer of 1925 an experimental filter plant with a capacity of 150 000 gal per day was designed and built for the express purpose of studying the phenomena of mixing and settling. This plant was composed of rectangular wooden tanks supported on a concrete mat foundation and enclosed in a light frame structure. The plant was arranged so that a reasonable range of times and velocities of mixing and a wide range of times and velocities in coagulation basins could easily be obtainable by making slight alterations. Two identical filter units were provided for use as a measure of results.

After about six months' operation in parallel with the large filter plant, the experimental plant was placed in charge of Mr. Roberts Hulbert and Frank W. Herring, Assoc. M. Am. Soc. C. E., who began on the program of settling-basin studies and obtained some very good results; but certain peculiarities in these results led to an intensive search to determine the reason for incon-

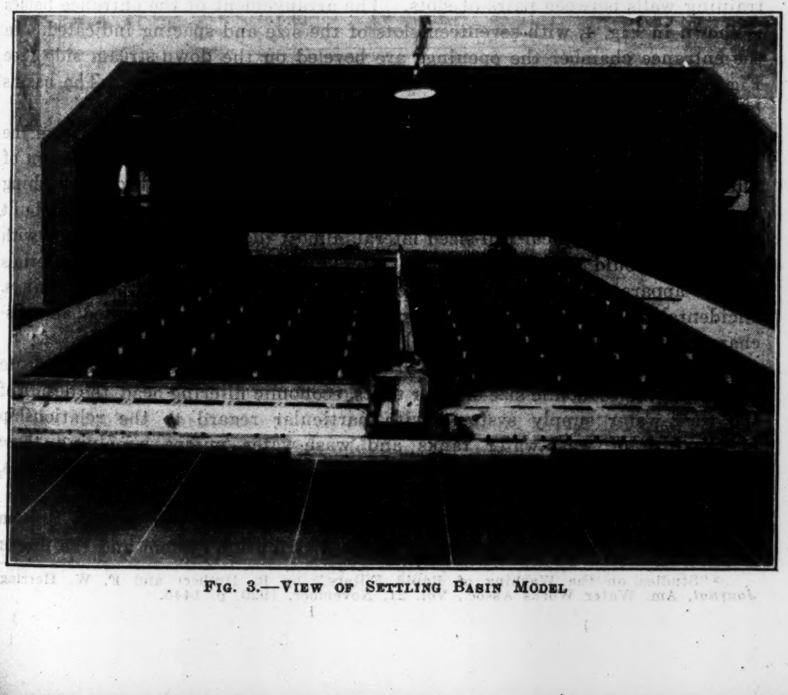

FIG. 3.—VIEW OF SETTLING BASIN MODEL

sistencies. Finally, the trouble was discovered in the fact that the two filter units used to measure the results were not washed uniformly. Having become absorbed in the development of better methods of washing filters, the remainder of the time available for the experimental filter plant operation was spent on this subject and a technique was developed of washing them to a certain definite sand expansion, instead of at the usual constant rates of wash-water flow.[3]

Scale Model Tests of Settling Basin Inlets.—Concurrently with the operation of the experimental filter plant, investigations of flow in settling basins were made by the use of a 1 : 25 scale model replica of the basin proposed to be used at the Springwells Plant. This model (see Fig. 3) was the means of determining the detail of inlet and outlet construction required to give a uniform distribution of flow across the full width of the basin and the longest actual retention period, as determined by floats, dyes, and salt solutions. Potassium permanganate dye was most satisfactory in determining the condition and distribution of flow by observing the advancing cloud of colored water. The time element was denoted by plotting the front edge of the color cloud at the end of each minute after the application of the color until it flowed out at the outlet. This plotting gave a record of each run, such as the typical form shown in Fig. 4.

The outlet conditions were early found to have little effect on the flow distribution. Therefore, attention was concentrated on the inlet detail. From the test results on the model, a vertically slotted wall inlet was adopted, with training walls between pairs of slots, The arrangement of the entrance baffles is shown in Fig. 4, with seventeen slots of the size and spacing indicated. In the entrance chamber the openings are beveled on the down-stream side (see Fig. 4(*b*) and Fig. 4(*c*)). Guide-vanes were of galvanized iron. The basins have "straight-through" flow.

Filter Under-Drain Lateral Experiments.—To determine how uniform the distribution of wash-water flow would be from a tentatively adopted design of filter under-drain lateral and to develop a low-cost brass, or bronze, bushing for the perforations in the under-drain laterals, a testing apparatus was built adequate for one typical full-sized lateral, almost identical in dimensions with those that would go into the actual filters. Several types of pipe materials in this apparatus, were tested, as well as types of perforations and bushings. Incidental to this test, a series of submerged orifices was calibrated and discharge coefficients were obtained.

Analytical Investigations and Studies.—Analytical studies were made to determine the economic size of filter units, economic filtering head, the design of the wash-water supply system (with particular regard to the relationship of the size of wash-water tanks and wash-water pumps supplying those tanks), and the costs of types of filter bottoms, wash-water trough materials, and chlorine-handling equipment.

General Basis of Design.—The ultimate capacity of Springwells Station was determined by a detailed study of the distribution system and the proper division of load among the three plants designated by the consultant's report of 1924.[3] This report and the results of experimental work and preliminary studies, together with previous experience, led to adoption of values given in Table 1, as the basis of design for the Springwells Filtration Plant. The design required, furthermore, that coagulants should be applied to the initial mix at the pumps or the meters and that the mixing be by mechanical agitators. The design of the details of the settling basins was determined by scale model studies (see Fig. 4). The filter bottom specified was the perforated-pipe grid type with a center manifold.

	(*e*) STRUCTURAL LOADS AND STRESSES	
	Weight, in Pounds per Cubic Foot:	
26	Water	62.5
27	Earth	100.0
28	Concrete	150.0
	Maximum Allowable Unit Stress, in Pounds per Square Inch:	
	(1) Tension in reinforcement, for:	
29	(*a*) Floors, walls, and footings	16 000
30	(*b*) Roofs and columns	18 000
	(2) Compression in concrete, for:	
31	(*a*) Floors, walls, and footings	650
32	(*b*) Roofs and tied columns	750
33	(*c*) Circular columns with spirals	1 000
34	Maximum allowable load on a bearing pile, in tons	25
	Maximum Allowable Bearing Value of Earth Foundations, in Tons per Square Foot:	
35	(*a*) Filtration plant structures	0
36	(*b*) Reservoir	1

Horizontal earth pressures were assumed to be equivalent to hydrostatic pressures, plus surcharge when imposed. Live loads were determined by conditions in substructures; in superstructures, live loads were determined by conditions, or by reference to the Detroit Building Code, whichever was the higher.

DESCRIPTION OF PLANT

General.—The keynote of the entire design is practical simplicity. Attention was given to each detail to avoid complex situations which would be costly to build, or which later might cause trouble in operation and maintenance. Where auxiliaries have been used, such as master control for filters, summation devices for meters, float-controlled water-level indicators, float controls for pumps, etc., they have been installed so that their discontinuance from service will not interrupt the operation of the plant or affect the functioning of the standard equipment with which they are used. As a rule, automatic devices, such as the differential chemical feed, the automatic filter shut-off, the proportional chlorine feed, etc., have been avoided, preference being given to manual control where practicable.

The construction of the conduits, chambers, basins, filters, and reservoirs, is of reinforced concrete. The superstructures have structural steel frames encased in concrete (with the exception of the steel frame of the Chemical Building which is only partly encased), reinforced concrete roofs insulated with cork and tar and gravel roofing, and hollow-tile curtain-walls faced on the outside with Indiana limestone and on the inside with terra cotta, glazed brick tile, or glazed hollow tile. The operating floors of the filters are finished with 6 by 6-in., red, quarry tile with dark green terrazzo borders. The floors in the Chemical Building, storage rooms, etc., are finished with concrete hardened with granite chips and ground smooth.

The entire structure is supported on a foundation of wooden bearing piles driven to hardpan through a subsoil of plastic and soft blue clay. The total load averages 20 tons per pile with the piles arranged so that, when the plant is entirely filled and loaded, there is a variation of not more than 5 tons per pile. On account of the unfavorable subsoil conditions, care was taken to avoid excessive concentrations of loads in the plant. Some variation in loading is occasioned by fluctuating live loads, such as in storage bins, basins, filters, and wash-water tanks.

Chemical Plant.—The Chemical Building is over a part of the mixing chambers, and contains the chemical storage tanks, chemical unloading and conveying equipment, the dry-feed machines, and hoppers for dosing ground sulfate of aluminum and ammonium sulfate. The arrangement of chemical equipment is shown in Fig. 5. This equipment is arranged so that, by a minimum of revision, the manufacture of aluminum sulfate may be provided for, at the same time preserving the dry alum equipment for stand-by service. The provision for alum manufacture contemplates making the alum syrup and feeding it as a solution.

The design of the Chemical Plant was based on the following capacities:

(1) At maximum demand, a storage capacity of 30 days' supply of raw materials.
(2) At normal demand, a storage capacity in each alum feeder bin, of 1 day.
(3) At maximum demand, a storage capacity in solution feed tanks, of 1 day.
(4) At maximum demand, a storage capacity for alum syrup, of 3 days.
(5) Unloading equipment to handle a 40-ton car in 8 hr.
(6) Reclaiming conveyors sufficient to handle 1 day's supply in 3 hr.

The equipment installed in the Chemical Plant consisted of the following:

(1) Suspended steel storage tanks of 390-tons total capacity consisting of:

(*a*) Four storage tanks at 60 tons capacity each.
(*b*) Three storage tanks at 30 tons capacity each.
(*c*) Five feeder hoppers at 12 tons capacity each.

(2) Pneumatic conveyor for unloading from railroad cars and delivering to storage (capacity 5 tons per hr).

FIG. 5.—ARRANGEMENT OF CHEMICAL EQUIPMENT

(3) Screw conveyor, 200 ft long, for reclaiming material from storage tanks (capacity 5 tons per hr).

(4) Bucket elevator for lifting material from the reclaiming conveyor to the conveyor above the feeder hoppers (capacity 6 tons per hr).

(5) Screw conveyor for distributing material to the feeder hoppers (capacity 6.6 tons per hr).

(6) Five dry-feed machines suspended from the feeder hoppers.

(7) A weighing scale for each feeder hopper and dry feed machine, with 30-in. indicator dial and recorder.

(8) A dissolving basin for each dry-feed machine, delivering to the chemical dosing lines.

(9) Three 3-in. dosing line headers of 99% pure copper extra heavy tubing, with stream-line fittings and valves of bronze composition resistant to the action of the alum solution.

Raw-Water Conduits and Meters.—The raw water is delivered to the mixing chamber through two 10 by 8-ft concrete conduits which run under the floor of the generator room in the power plant. At the west side of the power plant the conduits change shape to 9-ft square conduits and slope upward on a grade of about 12 per cent. In this section, a distance of about 60 ft, a raw-water meter is installed in each conduit. These meters are of the Venturi type with 9-ft square inlet and outlet ends and 4-ft square throats. The meters are cast of concrete with bronze-lined iron throat and pressure-ring castings and bronze-lined cast-iron inlet pressure rings set in the concrete. The raw-water meter registers are in a passageway of the building convenient to both alum and chlorine feeders. Dosing points for coagulating chemicals and chlorine are provided at both inlet and outlet ends of the meter tubes. In the design of the meter tubes advantage was taken of the upward slope in the conduits so as to compensate for their convergence in such a way that no air is trapped, on filling the conduits, and all water may be drained out, on emptying the conduits.

Mixing Chambers.—The dosed raw water enters the mixing chambers from the down-stream ends of the two parallel raw-water meters. The mixing chambers are in three units of approximately 5-min retention period, each with a by-passing channel. The general arrangement and details are shown in Fig. 6. The water enters the by-passing channel on the east side which is equipped with gates to shut off or admit water to any of the three chambers. Normally, the water enters through the three 6 by 10-ft sluice-gate inlets to the south chamber, flows northward through the three chambers (the dividing wall-gates of which are normally open) and leaves through the three 6 by 10-ft gates at the northwest corner into the coagulated water conduit to the settling basins.

All the sluice-gates in the mixing chambers are of the rising stem type, and are hand-operated, with worm-geared floor stands. While it is in the mixing chambers the water is stirred by mechanically driven paddles rotated at a peripheral speed of 0.67, 1.0, 1.33, or 2 ft per sec, the speed being regulated

FIG. 6.—PLAN AND DETAILS OF MIXING CHAMBERS

to give the best conditioning of the water. At present (1934), only the first mixing chamber is equipped with agitators, and brick baffle-walls have been built in all three chambers. As the plant load is increased the other chambers will be equipped with agitators. The location of the mechanical agitator units for the south section of the mixing chamber is indicated in Fig. 6. Steel-plate paddles, 10 ft long, are mounted spirally about a shaft of 12-in. steel pipe hung from a thrust-bearing in a base casting mounted on the cover slab of the chamber. The lower end of the shaft is steadied in a sleeve-bearing attached to the bottom of the chamber sump. This paddle assembly is driven through a 900:1 vertical reduction gear by a four-speed squirrel-cage vertical motor mounted on the gear housing.

The following data will serve as a summarized description of the mixing chamber:

Elevations, in Feet, Above:	
High water	131.6
Normal water	131.1
Bottom Slab:	
At wall line	112.5
At edge of sumps	110.0
Volume of water, in million gallons	3.201
Average dose of alum, in grains per gallon	0.6
Time of mixing, in minutes, at 300 mgd capacity.	15
Length of horizontal travel, with baffles, in feet (approximately)	1 000
Velocities, in Feet per Second:	
Of horizontal flow, at 300 mgd capacity	1.11
Of agitators (peripheral)	0.67 to 2.0
In gates	2.5 to 4.0

Settling Basins.—The general features of the settling basins are shown in Fig. 7. Referring to Fig. 8, column vanes are 12 in. thick at Elevation 112.5 and 6 in. thick at the top, from Point *A* to the entrance baffle. Intermediate vanes are 6 in. thick at the top and 12 in. at Elevation 112.5 for their full length and the batter continues to the top of the vane.

The settling basins are in four units each about 135 by 340 ft in plan, with about 18 ft of water depth and 5 ft of free-board from the water surface to the top of the roof slab. The entrance wall, or inlet structure, consists of a lower conduit, 10 ft 8 in. wide by 12 ft 3 in. deep, which extends the full width of the four basins, and an upper channel which distributes the water across the width of each basin by means of vertical slot openings in its inside wall. At two points, one between each pair of basins, there is a junction chamber which allows the water to flow up from the lower conduit into the upper channel or inlet of each respective basin. Each inlet channel entrance is provided with a 9 by 12-ft. sluice-gate. The inlet channel and slotted openings were constructed as nearly as possible similar to the most favorable inlet design obtained in the scale model tests previously mentioned.

The water distributed across the north end of each coagulation basin by the slotted openings in the upper entrance channel is directed straight

FIG. 8.—PLAN AND ELEVATION OF SETTLING BASIN INLET

through the basin by straight vanes, or by training-walls about 29 ft long. The water flows at a velocity of 2 to 3 ft per min for the 340 ft to the south end of the basins, where it is taken off over a weir. The weir is normally submerged about 1½ ft, into a collecting conduit, 11 ft 6 in. wide by about 10 ft deep. The collecting conduits flow together at two points into junction chambers which admit the water to the Filter Building. Each collecting channel outlet is provided with a 9 by 12-ft sluice-gate for shut-off purposes. Beneath the collecting conduits is a by-pass conduit, 11 ft wide by 6 ft 6 in. deep, extending the full width of the basins, through which water may be by-passed directly from the mixing chamber to the filters. This conduit is also an equalizer of the flow from basins to the two filter influent mains. At the outlet weir there is a skimmer baffle and trough of somewhat unusual design, so constructed that, during short periods of high-water level in the basins, the collected scum will flush off into the drain. The skimmer trough acts also as an overflow.

To facilitate cleaning, the bottom of each basin is shaped into three shallow hoppers, with a sump at the center of each. A hydraulically operated 24-in. mud valve is operated on the basin drain line in this sump. The valves on the pressure lines for operating the mud valves are grouped in the two, outlet, junction-chamber, gate-houses. One basin is equipped with a perforated belt line of small pipe for flushing the floor during cleaning. If this proves efficient the other basins will be so equipped. A water main with hose connections is provided in each basin for use in cleaning.

Structurally, the basins are of simple reinforced concrete design; the side walls and division walls are of the cantilever type; the floor is of the flat-slab type; and the roof is a flat slab supported by cylindrical columns 30 in. in diameter, spaced 30 ft from center to center both ways.

The roof-slab spans are 30 ft square between intermediate panels; the end panels have reduced spans in the direction in which the continuity is broken by walls and expansion joints. Since flat slabs of 30-ft span are quite close to the maximum in common use, the analytical design was checked by a mechanical instrument simulating a model of the structure.

The inlet and outlet wall structures are of somewhat special construction, as typical of such features: Inlet and by-pass conduits are designed as rigid monolithic structures; the slotted inlet wall, subject to little horizontal load, is designed as a curtain-wall or baffle, tied at the top, bottom, and ends; the outlet weir wall is a cantilever; and the junction chambers have horizontally spanned walls.

The roof of the basins is covered with 2 ft of fill, consisting of 6 in. of pea gravel and 18 in. of earth. Over each junction chamber is a gate-house superstructure in which the 9 by 12-ft sluice-gates are hoisted by electricity and stored. The part of the basins above the general finished grade of the site (Elevation 130.0) is faced with limestone to match the building group, and the curb wall retaining the basin roof fill is surmounted by an ornamental iron fence with stone posts.

The following data will serve as a summarized description of the settling basin:

Elevations, in Feet, above Detroit City Datum:	
High water	131.0
Normal water	130.6
Bottom Slab:	
At wall line	112.5
At edge of sumps	107.0
Crest of outlet weir	129.0
Volumes, in Cubic Feet:	
Water in each basin (Elevation 112.5 to Elevation 131.0)	844 770
Sludge hoppers, below Elevation 112.5	86 675
Total capacity in four basins:	
With water at Elevation 131.0	3 725 780
With water at Elevation 130.5	3 634 460
Number of basins	4
Time of detention at 306 mgd capacity, in hours	2
Velocity of flow through the basin, in feet per minute, at 306 mgd capacity	2.8
Velocities, in Feet per Second, at 306 mgd Capacity:	
Entrance velocity (normal water level)	1.0
Outlet velocity over weir (normal water level)	0.6
Maximum velocity in basin outlet channel	1.0
Turbidity of settled water, in parts per million.	10 to 15
Dimensions, in Feet:	
Length of flow in basin	340.0
Width of one basin	135.5
Effective water depth, one basin	18.0 to 18.5

Slotted entrances and 29-ft guide-vanes constitute the baffling system; the outlet of the basin is operated as a submerged weir; and the basins are covered.

Filters.—The group of sixty-eight filter units is adjacent to and centers on the south wall (which is the outlet end) of the settling basins. The filters are arranged in four rows along two parallel pipe galleries with concrete influent conduits connected by cross-conduits to the outlet chambers of the settling basins. The top slab of the influent conduits forms the operating floor between the rows of filters.

The interior of a filter unit showing the wash troughs and the under-drain system before the filtering material is placed, is shown in Fig. 9. The filters are of the front gullet type, with longitudinal wash troughs of cast iron and perforated cast-iron pipe under-drains. The under-drain laterals are connected to a central manifold cast in the concrete bottom of the filter. The ends of the laterals at the side walls of the filter unit are connected by 4-in. cast-iron headers parallel to the walls to eliminate dead ends and to assure more uniform distribution of flow in the under-drain system. These wall headers are perforated also to give a slight excess of wash water along the filter walls, during washing.

The filtering medium consists of an 18-in. depth of specially selected gravel and 20 in. of silica sand. The gravel grades in size from 3 in., maximum diameter at the bottom, to $\frac{1}{16}$-in. particles at the top of the gravel layer. The sand is 95% pure silica having an effective size of 0.5 mm and a uniformity coefficient of 1.3; 2% of it is composed of particles larger than 1 mm. The sand finer than 0.3 mm was washed out and is disregarded in computing the effective size and uniformity coefficient.

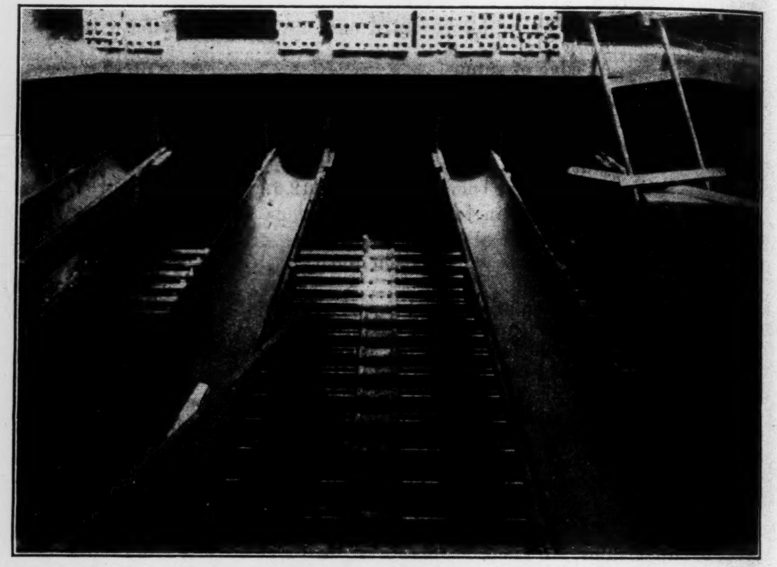

FIG. 9.—VIEW OF INTERIOR OF FILTER, SHOWING UNDER-DRAIN SYSTEM AND WASH TROUGHS

While it is filtering, water normally stands within 6 in. of the top of the filter walls, making about 7 ft of water depth on the surface of the sand bed. In washing, the sand expands 50% and rises to the bottom of the lower ends of the wash troughs.

A typical section of the pipe galleries and the piping for a typical filter unit is shown in Fig. 10. All header conduits are of concrete and are arranged to form the floor of the pipe gallery as well as the filter operating floor above. The filter connections are made with cast-iron fittings and flanged valves of the following sizes (in inches):

FIG. 10.—PIPE GALLERY DETAILS, FILTRATION PLANT

All valves are of the cast-iron, bronze-mounted, double-disk type, actuated by hydraulic cylinders operated from a marble-faced operating table or cabinet located on the filter operating floor at the front of each filter. All hydraulic cylinders are bronze-lined throughout, including the cylinder heads and pistons, and all pressure piping to the valve cylinders is of seamless copper tubing.

Each filter is equipped with a rate-of-flow controller of the Venturi type and a loss-of-head gauge, both actuating an indicating and recording gauge head mounted on the filter operating table above. The rate controllers are arranged for master-control setting or for individual setting as desired. The pipe galleries are heated by steam radiators and ventilated by a line of steel grating along each side of the operating floor of the filter.

The wash-water supply system consists of two pumps with capacities of 6 000 gal per min each, two pumps with capacities of 8 000 gal per min, located in recesses off one pipe gallery, and two 50 000-gal tanks in the cross-monitors of the Filter Building. The pumping capacity is sufficient for washing filters continuously, one at a time, while the tank capacity is sufficient for one single-filter wash. The depth of the wash-water tank and the rate of filter washing are indicated on a large illuminated gauge near the center of each operating gallery.

The following data will serve as a summarized description of the filters:

Rate of Filtration, in Million Gallons per Day, per Acre:	
Maximum	180
Normal	160
Number of filter units	68
Capacity of a filter unit (maximum rate), in million gallons daily	4.5
General Dimensions, in Feet:	
Width of sand bed	27.00
Length of sand bed	40.33
Depth of filter box	11.0
Clear distance between troughs	4.44
Height, bottom of wash-water tank above sand surface	35.5
Detail Dimensions, in Inches:	
Diameter of connections:	
Influent	36
Effluent	24
Wash water	24
Drain	30
Re-wash	8
Thickness of sand bed	20
Gravel:	
Thickness of layer	18
Maximum size	3
Minimum size	$\frac{1}{16}$
Height, surface of sand to crest of wash troughs	40

Elevations, in Feet, above Detroit City Datum:	
Bottom of filter	120.0
Water surface on filters	130.5
Effective size of sand, in millimeters	0.5
Uniformity coefficient of sand	1.3
Under-Drains (Dimensions, in Inches):	
Laterals, size	4
Laterals, spacing, center to center	12
Orifices, size	0.504
Orifices, spacing, center to center	6
Ratio of orifice area to sand area (× 100)	0.277
Rate of washing, in inches per minute	30 to 39
Tank capacity for wash water, in gallons (net)	95 000
Pump capacity for wash water, in gallons per minute	28 000
Percentage of wash water used (average)	1.3

The strainer system is composed of perforated cast-iron pipe, with perforations brass bushed. The wash gullets are at the front of the filters, and the sand is not agitated during the washing process except by the high velocity of the wash water.

Filter Building.—The filter group housed in a single-story building with two longitudinal monitors, over the filter operating galleries, and two cross-monitors in which the wash-water tanks and air-conditioning and heating equipment are placed. This building is of concrete-encased, structural-steel frame construction, with reinforced concrete roof of the ribbed-slab type. The curtain-walls are of hollow tile faced with buff terra cotta on the interior and chat-sown Indiana limestone on the exterior.

The concrete ceiling and columns are painted a light cream color. The operating floor is finished with 6-in. square, red, quarry tile, laid in black mortar, with borders and spill-rail curbs of dark green terrazzo. A railing of ornamental iron with an oak top rail is along each side of the operating galleries. All ornamental iron work, steel floor gratings, ventilator grilles, and steel sash and door framing are painted a dark green. The roof is insulated with a 1½-in. layer of pressed cork on top of which is standard 4-ply tar and gravel roofing. Large skylights of the vault type in the roof over the filters augment the light from the gallery monitors.

Heating System.—Considerable attention was given to the heating and ventilating of the Filter Building. Tests made in the existing Water-Works Park Plant indicated considerable variation in temperatures throughout the building and a large consumption of heat to maintain an average of 50° F during zero weather. Condensate was seen to collect on the steel work, roof slabs, and window sash in the spring and fall when the building was not heated. With this example to observe and test, it was expected that an improved heating and ventilating system could be devised for the Springwells Filtration Plant. The uncertain heat loss to the open water surface of the filters complicated the problem considerably. Attempts to measure this loss failed, due to lack of instruments for measuring such a small temperature change. A heat transfer coefficient of 2.00 was taken as the most probable for heat loss to an open water surface. In collaboration with experienced heating and ventilating consultants, the following outline of a heating system for the Springwells Filter Building was developed.

Heating.—The pipe galleries were to be heated by direct radiation; and the main building (except one room), by re-circulated air. The controlling temperatures, in degrees Fahrenheit, were:

Maximum average, controlled to	70
Minimum, average	50
Maximum allowable variation in working area	20
Maximum temperature of heated air	90

Ventilation.—The specifications required four changes of air per hour, re-circulated, with one change of fresh air admitted and tempered. Stale air was to be exhausted from the floor, at the ends of the pipe galleries, at the rate of ½ air change per hr. A probable air leakage of ½ air change per hr from the building was expected, due to maintaining inside the building, by means of the fans, a slightly higher pressure than normal atmospheric pressure. Re-circulated air was to be taken from the main roof at the center of the filter group and returned at the four intersections of the operating galleries, and at the cross-galleries. Maximum permissible air velocities, in feet per minute, were established as follows:

In air ducts	600
At outlets of fans	1 600
Through heaters	1 000

The total heat required to maintain the main part of the building at an average temperature of 50° F, with zero temperature outside, and with water at 32° F in the filters, was computed as 6 846 900 Btu per hr. This heat loss was apportioned as shown in Table 2. The loss in the pipe galleries could be estimated only approximately. Considering the exposed area of pipes as condenser surface and estimating 1 air change per hr due to convection currents, a total of 587 600 Btu per hr was computed as necessary to keep the pipe galleries above 50° F, with water at 32° F in the plant, and the main building at 50° F.

TABLE 2.—HEAT REQUIRED TO MAINTAIN THE FILTER BUILDING AT 50 DEGREES FAHRENHEIT, WITH 0 DEGREES FAHRENHEIT, OUTDOORS

Surface	Area, in square feet	Heat, in British thermal units per hour	Surface	Area, in square feet	Heat, in British thermal units per hour
Glass	7 163	526 690	Skylights	9 360	598 000
Walls	33 681	450 510	Water	80 784	2 586 000
Roof	101 744	874 800	Floor over conduits	21 960	131 400
For 1 air change (1 608 000 cu ft) per hr					1 679 500

The heating surface required was computed on the basis of 5-lb steam pressure in the heaters and radiators. An allowance of a 2-lb pressure drop in the steam lines between the source of the steam (the low-pressure side of the turbines in the generator room of the power plant) and the farthest heater, governed the sizes of steam pipes.

The heating equipment consisted of the following principal units, complete with accessories:

Four blower fans of 33 500 cu ft per min capacity of air at 70° F against a back pressure of $\frac{7}{8}$ in. of water.

Four batteries of cast-iron heaters having 2 064 sq ft of heating surface each, for re-circulated air.

Four batteries of cast-iron heaters having 408 sq ft of heating surface each, for tempering fresh air.

Four dampered louvers for fresh-air intakes.

Four distributing louvers or diffusers for re-circulated air.

Four exhaust fans of 4 000 cu ft per min capacity of air at 70° F against a back pressure of 0.3 in. of water.

Twenty-eight radiators in pipe galleries, each of 126-sq ft heating surface.

Two vacuum return pumps for pipe-gallery radiation, each of capacity ample for 5 000 sq ft of radiation.

The re-circulating fans and air heaters are installed in the space beneath the wash-water tanks in the cross-monitors of the building. Condensed steam returns by gravity from the air heaters to a vacuum return pump in the basement of the plant office, which is on the route back to the boilers.

The steam main to the air heaters in the monitors is installed on the roof of the Filter Building with the air-recirculating duct. The steam supply lines to the pipe galleries are placed along the walls of the galleries. All steam lines and return lines are insulated with 85% magnesia pipe covering, re-canvassed. An exposed part of the steam main on the roof is also covered with a steel sheath. The heating system was installed during the time of interior finishing and was completed soon after the building was constructed.

Office and Laboratory Building.—This building was constructed complete under one general contract, including heating, ventilating, plumbing, electrical work, and all other trades. Its construction was typical of buildings of this nature.

The first floor contains offices in front for the filter plant superintendent, the power and pumping plant superintendent, the clerical force, and a conference or receiving room. The rear of the first floor contains locker rooms, shower rooms, and toilets for the plant workmen and operators, as well as a time office and storage rooms. The second floor contains the filter plant laboratory, with offices for the chief chemist and bacteriologist.

Weir Chamber.—It was required that the effluent water level be maintained at a height sufficient to submerge the filter-effluent connections and effluent-main conduits and to operate the shunt system.[4] For this purpose, a chamber is provided, at the outlet ends of the filtered-water, effluent-main, conduits, which contains a filter-seal weir with crest at Elevation 118.00 and a reservoir weir, in two sections, with crest at Elevation 119.50, as shown in Fig. 11. This chamber is of reinforced concrete construction. In addition to its operating function it serves as a foundation for the plant office as well as providing storage space for stop-logs, spare parts, castings, etc. The two sections of reservoir weir are built diagonally to gain length and also to converge the flow from the filter-seal weir to the entrance of the conduits leading directly to the high-lift pumping plant. A central division wall is provided for use in shutting off one-half the plant. Openings in this division wall and in the reservoir-weir walls (filled by stop-logs) are provided for flexibility in bypassing or running under special operating conditions.

FIG. 11.—SECTIONS OF WEIR CHAMBER

Two 9 by 9-ft conduits which run from the weir chamber to the west end of the high-lift pumping plant, are designed to carry water direct to the pumping plant. An 8 by 8-ft conduit conveys water from the south end of the weir chamber to the filtered-water reservoir. The conduits to the pumping plant take the water that overflows the filter-seal weir, while the reservoir conduit takes the water that overflows the higher reservoir weir.

The Shunt System.—The shunt system is a method of operating the high-lift pumping plant so that about three-fourths of the total pumpage is drawn directly from the filter plant at about 1½ ft above the level of the effluent-seal weir, while the remainder, which is taken on the daily peak, is drawn from the filtered-water reservoir at a level that may vary with the reservoir stage, from Elevation 120.0 to Elevation 108.0 each day. Thus, considerable head on the suction side of the pumps is conserved for most of the water pumped. This is accomplished by dividing the pumping units into two groups with a division wall in the suction gallery of the pumping plant. A small group at the remote end from the filter plant, comprising about one-fourth of the high-lift pumping capacity, draws from the reservoir through Gate Chamber No. 1 and reservoir-outlet conduits connected to the east end of the pump suction gallery, while the remainder of the pumps draw directly from the filter plant, *via* the weir chamber.

The weir chamber effects the division of the water at the filter plant by a secondary weir, called the reservoir weir, the crest of which is high enough above the seal weir so that the entire flow of filter effluent may pass over it without overtopping the reservoir weir. The direct flow to the high-lift pumping plant is taken off between these weirs. Thus, the entire capacity output of the filter plant may pass directly to the high-lift pumps without affecting the reservoir levels at all. If the pumps taking suction direct from the filter plant do not require the full filter output, the effluent level rises until it overtops the reservoir-weir crest at Elevation 119.5, and the excess is discharged to the reservoir. During peak pumpage hours, when the output of the high-lift plant is more than that of the filter plant, pumps at the remote end are placed in service as required to meet the demand, and the pumpage in excess of the filter output rate is taken from the reservoir.

For convenience in operating the pumps, a water-level gauge is provided in the weir chamber between the two weirs and a control level of about Elevation 119.50 is maintained at this point. If this water level rises above Elevation 119.50, it is known that water is flowing into the reservoir and that, if possible, additional work by the pumps west of the division wall is permissible and less on the east side of the division wall is in order. If the control water level falls to Elevation 119.0, or below, less pumping west of the division wall, and more, east of the division wall, is desirable. To safeguard the operation of the pumps and to insure suction water from the reservoir to all pumps in the high-lift plant, flap-gates are provided in the suction-gallery division wall which are opened by the pressure from the reservoir-water side at any time the water level on the filter-plant side is below that on the reservoir side of this wall.

From the foregoing it is seen that by the shunt system the main flow of water from the filter plant is diverted directly to the high-lift pumps at a normally constant high level, and the reservoir is on a secondary loop, or shunt, feeding a small group of pumps, normally isolated as to suction from the remainder of the station. Experience with the shunt system at the Water-Works Park Station (see Fig. 1) has shown that it causes no inconvenience whatever in the pump operation. The pumps in the reservoir group, as a rule, are put in service only in peak hours and little concern is given the shunt system, which works automatically.

Hydraulics of Flow Through Plant.—The computed velocities, head losses, and water-surface elevations at governing points throughout the plant are given in Table 3 for both a maximum-capacity flow of 306 000 000 gal daily, and an average-capacity flow of 210 000 000 gal daily. For these computations it is assumed that the water-surface elevations in the filtered-water reservoir are less than 119.5. When the reservoir is at higher stages, up to its normal high-water level of Elevation 121.00, the filter effluent levels will be raised correspondingly (except for the slight effect of the greater submergence of the effluent weir), thus reducing the available operating head of the filters at times of high water in the reservoir.

Under-Drainage System and Main Drains for Plant.—The entire sub-grade area of the filtration plant and reservoir is provided with drains for controlling the elevation of the ground-water under the plant. The drains are of 6-in. vitrified sewer pipe laid with open joints in shallow trenches at the surface of the sub-grade and surrounded by open gravel. They are spaced approximately 7 ft from center to center, located so as to clear the piling. Under the coagulation basins and mixing chamber and under the floor-slabs of the filters there is also a layer of open gravel about 4 in. thick for distributing the water between the drains. There is no gravel layer between the drains under the reservoir. There are no drains under the wall footings and the pipe galleries. In addition to the under-drains there is also a belt drain of perforated, 12-in., cast-iron pipe laid completely around each structure at the top of the wall footings to intercept ground-water from the surrounding area.

The drainage system under the structures constituting the filtration plant is connected to the main drain from the plant by an overflow connection which discharges water when the level is above Elevation 118.5. It is expected that, usually, there will be a flow from the drains due to leakage and ground-water; but to assure a ground-water level at sufficient height to cover the timber piling a water-supply connection is provided with a float-operated valve that admits water to the drainage system when the level in it becomes less than Elevation 118.5 (which is 4 ft above the top of the highest pile).

The level in the reservoir drainage system is maintained at desired levels by float-controlled sump pumps which discharge into the sewer.

Filtered-Water Reservoir.—The reservoir for filtered water consists of two sections, each with a capacity of 20 000 000 gal, and each a rectangle, 455 ft long by 313 ft wide (interior dimensions). There will be a third section, eventually, of about the same size. Water flowing to the reservoir is distributed to the sections by a conduit, built along the north wall, which is connected to the sections through a gate-chamber in each one and also through an additional 66-in. inlet valve in the east section. In each gate-chamber are four 48-in. double-disk gate-valves, hand-operated by geared floor stands with cranks. The water may enter or leave through these valves. Flap check-valves are placed on the gate-valve openings in such a manner that the water flows in through the valves on one side of the center baffle-wall and out through the valves on the other side. By this means, water may be circulated through the reservoir sections, if desired. In the east section, the 66-in. valve serves as the inlet, and two of the 48-in. valves equipped with

FIG. 13.—GENERAL SECTIONS, FILTERED WATER RESERVOIR NO. 2

flap-gates serve as the outlet, to produce circulation around the baffle-wall. Figs. 12 and 13 give the general plan and sections of the existing sections of the reservoir.

The reservoir is constructed of reinforced concrete of standard design. The walls are one-way slabs spanned vertically between the base and the roof. The roof and floor are of typical two-way flat-slab construction with cylindrical columns spaced 20 ft center to center both ways.

The reservoir is completely back-filled and its roof is covered with 6 in. of gravel and 18 in. of earth. It thus forms the front-yard area of the station and will be landscaped and planted. Water is drawn from the reservoir to the pumps in the east end of the high-lift pumping plant through two, 8-ft square, concrete conduits running from Gate Chamber No. 1 to the east end of the suction gallery in this pumping plant.

CONSTRUCTION

General Plan and Administration.—In constructing the Springwells Filtration Plant and Reservoir, the Board of Water Commissioners acted somewhat in the capacity of a general contractor. Most of the equipment, valves, sluicegates, piping, and castings were purchased separately, and contracts for the

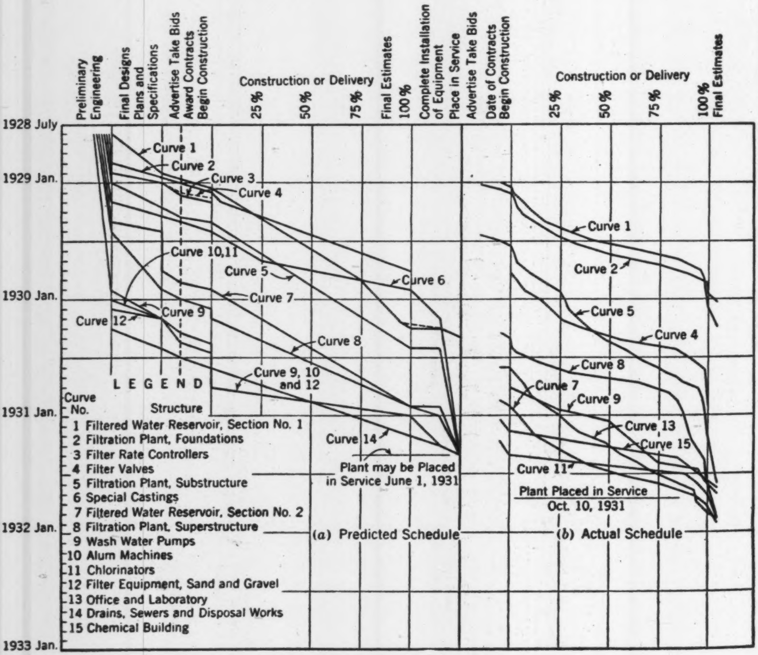

FIG. 14.—PROGRESS OF CONSTRUCTION

construction work and installation were let to building contractors and trades, this equipment, piping, castings, etc., being furnished. The reservoir was constructed under two contracts. The filtration plant was constructed under eight separate major contracts: (1) Excavation and piling; (2) substructure (mostly heavy concrete construction); (3) superstructure of Filter Building; (4) electrical work in Filter Building; (5) plumbing, heating, and ventilating work in Filter Building; (6) Chemical Building, including alum-handling equipment; (7) masonry facings of coagulation basins and mixing chamber and the construction of the superstructures of the drainage pump house and two gate-houses on the coagulation basins; and (8) complete construction of the Office and Laboratory Building.

The operating tables in the filtration plant, the chlorinators and chlorine piping, the chlorine scales, chlorine hoist, pressure water pumps and sump pumps, drainage pumps, filtered water meters, wash-water pumps, wash-water meters, and the wash-water pipes were furnished and installed under separate equipment contracts, let directly to the various equipment manufacturers.

The subdivision of the work resulted in smaller contracts and the letting of work directly to the proper trades. This eliminated considerable administration cost from the actual contracts, but required considerable administrative work on the part of the Engineering Division of the Board (which handled the work) with attendant expense reflected in the engineering cost figures, as shown in Table 4 discussed subsequently. It is believed that the savings in contract costs effected by this procedure considerably more than offset the increased administrative and engineering expense involved. Considerable saving in contract costs was obtained also by fully and completely detailing the contract drawings upon which bids were based, thus eliminating guesswork on the part of the bidders and resulting in low and close bidding. Dividing the work in this manner expedited the construction since construction was begun on the foundations while the plans were being completed for the superstructures and subsequent work. To schedule and expedite the various purchases and contracts properly, in order to prevent delays and to preserve harmonious working conditions where a number of different contracts were under way on the limited area of the site, involved careful attention both to the preliminary planning and to the progress of the work. It also added greatly to the duties of the engineering force.

Progress Schedule.—Before any purchase was made or contract prepared, a preliminary progress schedule of the complete project was made as shown in Fig. 14(*a*) by which it was estimated that the plant might be placed in operation by June, 1931. This schedule, of course, could not be followed exactly, but served as a guide in preparing the work. The actual construction schedule is similarly shown in Fig. 14(*b*).

The construction was completed to the point at which operation of the filter plant would have been possible July 1, 1931, if the water demand had required it. However, since the drop in water demand resulting from the general recession in business activity made the operation of the plant less urgent at the time, and since several miscellaneous items of work were desirable and more

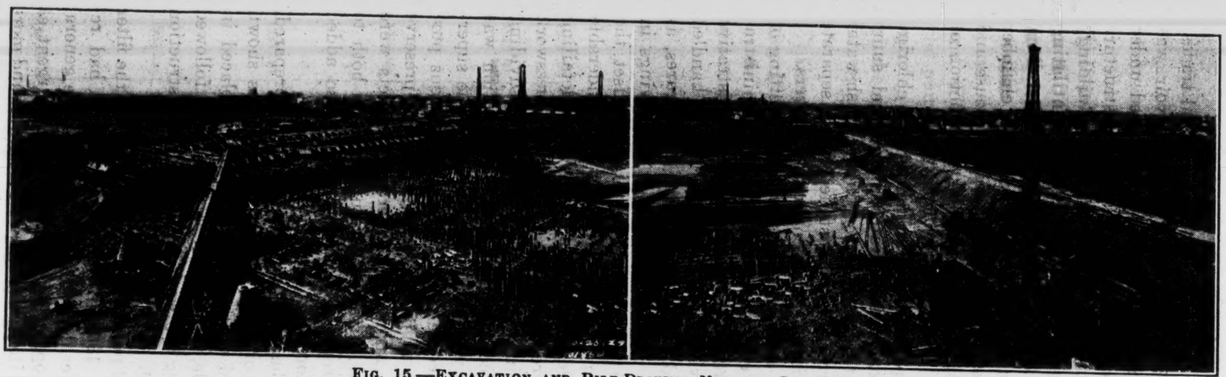

FIG. 15.—EXCAVATION AND PILE-DRIVING NEARING COMPLETION

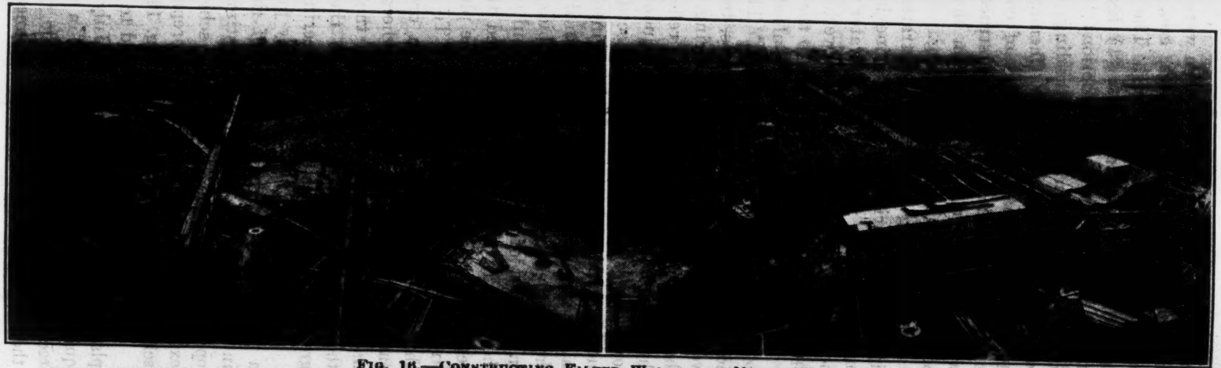

FIG. 16.—CONSTRUCTING FILTER WALLS AND MIXING CHAMBER

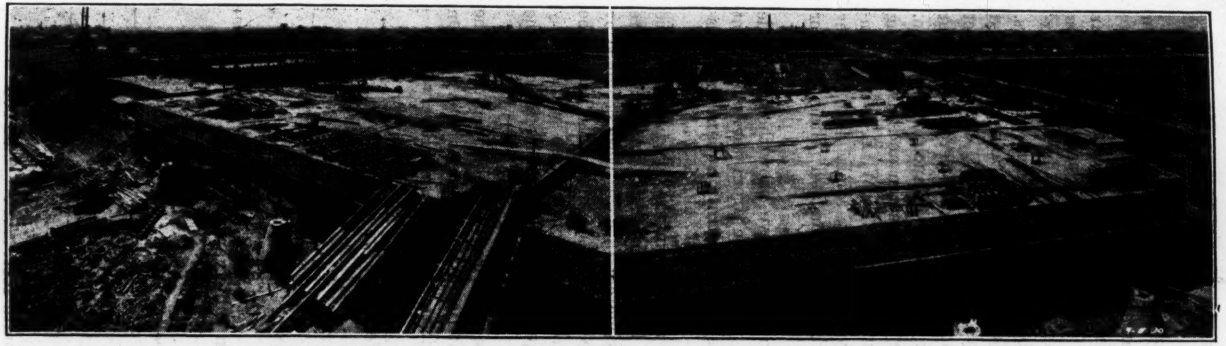

Fig. 17.—Extending Settling Basin; Filter Building Steel Work Erected

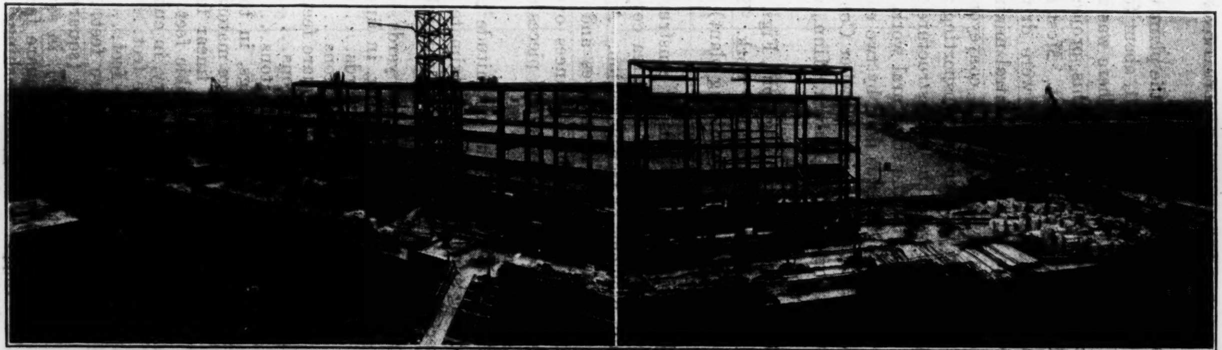

Fig. 18.—Chemical Building Steel Work Erected

economical to be done before the plant was put in service, the actual operation was begun on October 10, 1931, about four months later than scheduled.

Construction Methods.—There was nothing particularly special or peculiar about the construction of this project. Standard first-class construction methods were used throughout. Most of the excavation was by drag-line excavators and shovels. Piles were driven by ordinary wooden skid drivers. Concrete was mixed in a central mixing plant for each job and transported to the forms by chutes, belt conveyors, and industrial train, each contract making use of a different transporting method. The mixers were all of about 1 cu yd capacity. The superstructure work was typical of such construction. The major part of the structural work, except the excavation and pile-driving for the filter plant, was done by two contracting firms, the W. E. Wood Company and the Bryant and Detwiler Company, of Detroit, Mich. The Whitney Brothers Company, of Duluth, Minn., did the excavation and piling work for the filtration plant.

The construction photographs, Figs. 15 to 18, inclusive, show the magnitude and type of the construction work. They were taken from the same point (the top of the concrete mixing plant) and show the filtration plant in successive stages of construction.

The principal problems of construction arose from the magnitude of the project and the extent of the area covered by the plant structures, and were mainly problems of transportation. Approximately 18 acres were occupied by the actual structures themselves and large volumes of materials had to be handled for considerable distances over this construction area while many large pipe castings, valves, and pieces of equipment had to be installed as the work progressed.

A general idea of the magnitude of the work may be obtained from the following summary of the approximate quantities of the principal construction materials that went into the Springwells Filtration Plant and Reservoir:

Excavation, in cubic yards	420 000
Timber bearing piling, in linear feet	1 500 000
Concrete, in cubic yards	120 000
Reinforcing steel, in tons	7 200
Concrete forms, in square feet	2 000 000
Structural steel, in tons	1 120
Ornamental iron, in tons	70
Iron pipe and castings, in tons	2 000
Gravel fill and drainage material, in cubic yards	15 000
Tile under-drains, in linear feet	56 000
Stone masonry, in cubic feet	42 000
Brick and tile masonry, in cubic feet	77 000
Terra cotta, in square feet	33 000
Steel sash, in square feet	11 000
Metal doors, in square feet	1 000
Tar and gravel roofing (squares)	1 250
Skylights, (vault type), in square feet	11 000
Cork insulation, in square feet	134 000
Copper roofing and flashing, in square feet	35 000
Terrazzo and ground-concrete floors, in square feet	30 000
Quarry tile floors, in square feet	22 000

TABLE 4.—COST OF SPRINGWELLS FILTRATION PLANT

81	Engineering cost in percentage of total cost	8.53			

COST ANALYSIS

Before the beginning of any construction work on this plant, a Cost Accounting Bureau was organized with competent clerks and bookkeepers to keep complete records of the actual cost of the various features of the work as nearly as could be obtained by independently taking the time and material used in the work and checking where possible with the contractors' records. The costs of the main units of the plant as compiled from the account ledger are given in Table 4. These costs represent not only the contract costs, but also all costs incidental to the work, including force account work done by direct labor. The engineering costs include all design work, checking, preparation of plans and specifications, consulting architects' and mechancial engineers' fees, printing of plans and specifications, supervision of construction, time-keeping, clerical work, purchasing expense, checking of shop details, inspection of materials, shop inspection, and general administration of the work. The cost of experimental work is listed separately. For ease in comparing with other projects the costs have also been reduced to the basis as of the year 1913 by using the construction cost index figures of the *Engineering News-Record.*

ACKNOWLEDGMENTS

The design and supervision of construction of the Springwells Filtration Plant was done by the Filtration Bureau of the Division of Engineering formed by the Board of Water Commissioners of Detroit for this purpose. This Division worked under the general superintendence of George H. Fenkell, M. Am. Soc. C. E., General Manager and Chief Engineer, and F. H. Stephenson, M. Am. Soc. C. E., Engineer of Water System, of the Department of Water Supply. The Filtration Bureau was in the general charge of A. B. Morrill, M. Am. Soc. C. E., Assistant Engineer (Filtration), with the writer in charge of design, and J. W. Orton, Assoc. M. Am. Soc. C. E., Assistant Civil Engineer in charge of construction. Mr. J. C. Thornton, Architect, was responsible for the architectural work, and the E. R. Little Company, Mechanical Engineers, consulted on the heating and ventilating design. Mr. E. W. Frey, Accountant, had charge of the keeping of costs and records.

CONCLUSIONS

The execution of this project has contributed to the progress of water purification practice: (1) In the development of knowledge of the flow in coagulation basins and distributing inlet details by experimental model investigation (2) in the development of higher rates of filter washing and their control by sand expansion; (3) in the conception and development of the shunt system of operating filtered-water reservoirs; and (4) in the improvement of details, such as low loss-of-head rate controllers, summation of Venturi meters, perforated pipe filter under-drains, and chemical handling equipment.

DISCUSSION

F. H. STEPHENSON,[5] M. AM. SOC. C. E. (by letter).—Adequate and easily comprehended records of design and construction of large municipal projects, are not presented as frequently as they should be, and the author should be commended and congratulated for his contribution to this class of literature.

The writer's direct connection with the water supply of Detroit began with studies for the preparation of the Pratt report of 1919 mentioned by the author, and continued until after the beginning of operation of the Springwells Filtration Plant. With this background, the writer submits a few observations regarding the filtration of the water supply of Detroit.

The experimental filtration plant built in 1917 was designed primarily to give visual proof of the feasibility of filtering the existing water supply, and the improvement in appearance, taste, and purity which would be brought about by filtration. Its successful operation demonstrated that a satisfactory effluent could be produced with 2 hr. sedimentation and filtration at a normal rate of 160 000 000 gal daily per acre. The experimental plant constructed in 1925, was designed, as the author states, primarily to obtain information relating to the phenomena of mixing of chemical solutions with raw water, the formation of floc, and the settling of the treated water before it is conveyed to the filters.

The Springwells Plant, as built, retained the normal rate of filtration (160 000 000 gal daily per acre) and the 2-hr settling period found satisfactory in the older plant. Improved methods of introduction to, and guidance of, mixed water through the settling basins came as one of the results of lessons learned from the operation of the experimental settling basin. The designers of the new plant set their goal as efficient mixing of chemicals and raw water, with optimum floc and settlement of the treated water, in order to lighten the work of the filters.

The addition, to the filter under-drain system, of a line of perforated pipe connecting the ends of the lateral pipes, should result in improved distribution of wash water at or near the filter walls. The arrangement for operating the pumps supplying filtered water to the distribution mains, called the shunt system, should result in reduced power costs. Where conditions are favorable, this method of operation should find favor.

The methods of unloading, storing, mixing, and delivering of chemicals or chemical solutions are modern and labor-saving. Filter and wash-water control are effective and efficient. The general appearance and architectural treatment of the plant are pleasing, and the municipality possesses a filtration system of which it may well be proud.

ROBERT SPURR WESTON,[6] M. AM. SOC. C. E. (by letter).—The account of the construction of the new Filtration Plant at Detroit, Mich., by its designer, which has followed the "Studies on the Washing of Rapid Filters",[7] by Messrs. Roberts Hulbert and Frank W. Herring, is of great importance to those interested in the progress of the art of water purification.

[6] Cons. Engr. (Weston & Sampson), Boston, Mass.

The plant at Detroit exemplifies the great improvement which has been evolved in the method of acquiring a water purification plant in the past forty years. In the Nineties one bought a stock filter and tried to make it work with the water supplied to it. Some good ready-made fits were obtained, and some of the purchases—Biddeford, Me.; East Providence, R. I.; Elmira, N. Y.; Atlanta, Ga., and others—are still in use, although some have been "re-tailored" in order to fit their waters better. Many others of these ready-made plants have been replaced.

Now, as exemplified at Detroit, one studies the water to be treated and builds a plant to fit it. As the author has shown, the first requisite is proper treatment — coagulation. With proper treatment, almost any sand bed produces good results; without it, the excellent one designed by the author might fail even if it is true that the proper treatment of the Detroit River water is not as difficult as that of unstored, colored or turbid waters, such as those of the Dismal Swamp, the Ohio River, or the Mississippi River.

For example, with inadequately treated water, it probably would be impracticable, even at Detroit, to use sand as coarse as that having an effective diameter of 0.55 mm, or beds only 20 in. thick; also, it would probably be impracticable to use a system of pipes for under-drains.

Naturally, the ideal system in mixers and basins for chemical treatment and coagulation is turbulent mixing after the addition of chemicals, to be followed, in turn, by slow mixing and subsidence, the velocity of flow in basins roughly conforming to a decreasing parabolic curve which reaches its minimum just before the water is applied to filters. In practice, this ideal is approached "step-wise", but invariably there are pipes and channels between mixers and basins and between basins and filters in which velocities are increased even to a degree that damages flocs formed previously under favorable conditions.

In this connection, the designers are to be congratulated in maintaining in so large a plant, influent and effluent velocities of 1.0 ft per sec, which, while high in comparison with the velocity of 2.8 ft per min through the basins, are lower than those obtaining in many other plants. Especially praiseworthy is the simple system of distributing the basin influent, although in cases where silt-bearing waters are treated there is something to be said in favor of diverting the inflowing water toward the bottom of the basin; also, where colored waters are treated, there is something in favor of the parabolic deflectors near the outlet weir, so successfully used at Baltimore, Md.

In common with some others, the practice of the writer has tended toward the use of filters with false bottoms because they provide a better distribution of wash water. This is because the conditions more nearly approach the ideal of multiple orifices discharging from a large tank. Experience shows that great damage is done to sand beds for which the wash-water distribution is uneven, and unbalanced hydraulic conditions seem to arise in certain designs of pipe manifolds which no reasonable thickness of gravel beneath the sand seems to correct, although Gore, in Canada, has used layers of cemented gravel for this correction, with reported success.

---

[7] *Journal* Am. Water Works Assoc., Vol. 21 (1929), p. 1445.

The recent design of the Mahoning Sanitary District filters,[8] using false bottoms supporting Wheeler pyramids and balls, and providing a large accessible water space beneath, seems to be superior to any pipe system. The writer's firm has recently used it at Braintree, Mass., with entire satisfaction.

The selection of wash-water rates of from 30 to 39 in. per min for a sand having an effective size of 0.50 to 0.55 mm, is interesting to the writer because, in 1913, he made experiments at Concord, Mass.,[9] using various types of sand. From these experiments there was derived an optimum velocity of 30 in. for a sand having an effective size of 0.55 mm, at which velocity it was estimated the sand would expand 39 per cent. In these experiments, however, no attention was given to variations in viscosity of wash-water due to variations in temperature.

In conclusion, the writer expresses his admiration, not only of the simplicity of the design, but of the fullness of the data presented in the paper, data truly useful to designers and users of other plants.

Eugene A. Hardin,[10] M. Am. Soc. C. E. (by letter).—The favorable attitude of the discussers leaves the writer with very little excuse for a closure, except to express his gratitude. To complete the description of this plant it appears that a summary of operating results should be included. Therefore, the data in Table 5, taken from the March, April, and May, 1935, reports of

W. M. Wallace, Superintendent of Filtration, Department of Water Supply, Detroit, Mich., on the operation of both the Water-Works Park and the Springwells Filtration Plants are submitted.

Mr. Stephenson's reference to the architectural treatment may be appreciated from Fig. 19, a view of the plant interior. It should be explained, however, that the architectural features were placed secondary to the functional design features. The architect developed his design from a general layout and plant skeleton already planned and given to him for architectural treatment. With this handicap, architecturally, he succeeded commendably in obtaining a very pleasing appearance from the straight lines and mass of the structures with a minimum of embellishment and with the use of plain, and not unduly expensive, materials.

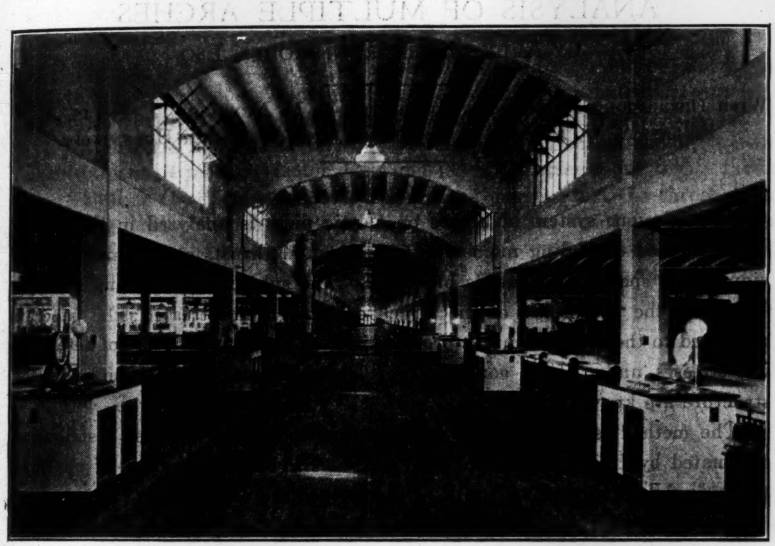

FIG. 19.—INTERIOR VIEW OF OPERATING FLOOR, SPRINGWELLS FILTRATION PLANT, DETROIT, MICHIGAN.

The writer agrees with Mr. Weston that the Wheeler bottom is a very desirable type of filter under-drain system. It was one of a number of types considered for the Springwells Plant, but was not adopted on account of its considerably greater cost than the perforated pipe under-drain system.

ANALYSIS OF MULTIPLE ARCHES

By ALEXANDER HRENNIKOFF[1], ESQ.

WITH DISCUSSION BY MESSRS. L. E. GRINTER, N. M. NEWMARK, T. Y. LIN, A. H. FINLAY, A. W. FISCHER, A. A. EREMIN, AND ALEXANDER HRENNIKOFF.

SYNOPSIS

A continuous system of arches on elastic piers is analyzed in this paper, and a method of finding moments and horizontal thrusts at the ends of individual arch spans and piers, is presented. The subject of designing multiple arches, in the wide sense of the term, "design," is not treated; the paper is restricted to the discussion of a problem in engineering mechanics of determining stresses under given conditions of loading when all dimensions of the structure are known.

The method is based on the well-known principle of moment distribution originated by Hardy Cross, M. Am. Soc. C. E.,[2] but the manner of applying that principle, and various details of the method are original.

OUTLINE OF THE METHOD

The proposed method may be divided into the following operations:

(*a*) Analyze the individual spans on the assumption that they are fixed-ended and, on this assumption, determine the end moments and thrusts for each arch.

(*b*) Find the unbalanced moments and thrusts at each pier-head by adding, algebraically, the fixed-ended moments and thrusts coming from two adjacent arch spans (referring to a specific example, it will be assumed in Fig. 1, that the unbalanced joint functions are present only at the pier-head, *C*, none being present at the joint, *B*).

(*c*) Determine a series of quantities that may be appropriately termed, "the end distribution factors;" they are similar to distribution factors and carry-over factors in the method of moment distribution, and their nature will be explained subsequently.

NOTE.—Published in December, 1934, *Proceedings*.

[1] Instr., Dept. of Civ. Eng., Univ. of British Columbia, Vancouver, B. C., Canada.

[2] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

(*d*) Determine the "joint distribution factors," four in number, which represent moments and thrusts at the joint with unbalanced forces, *C,* when it is given a unit rotation or a unit horizontal displacement by some outside agency. These joint factors are equal to algebraic sums of the respective end distribution factors (Operation (*c*)) for the three members meeting at Joint *C*.

(*e*) Distribute the unbalanced moment and thrust at Point *C*. This requires finding the rotation and horizontal displacement of Joint *C,* necessary to balance the forces at the joint, an operation involving the solution of two simple equations, or the construction of a diagram.

(*f*) Determine the resultant forces at the ends of all members.

Referring to Operation (*c*), there are four end distribution factors at each end of each member when the joint, *C,* moves (by member is meant each individual arch span or pier, so that, in all, there are five members in Fig. 1): (1) The rotation moment factor, m_α; (2) the rotation thrust factor, h_α; (3) the displacement moment factor, m_Δ; and (4) the displacement thrust factor, h_Δ. The first two factors are, respectively, the moment and the thrust at the end of any member such as Point *A* in Fig. 1, when Joint *C,* with an unbalanced fixed-ended moment and thrust, is given a unit rotation without any linear displacement. Similarly, m_Δ and h_Δ are moments and thrusts that occur when Joint *C* is given a unit horizontal displacement, without any rotation or any vertical displacement.

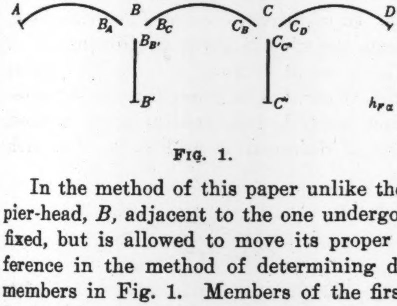

FIG. 1.

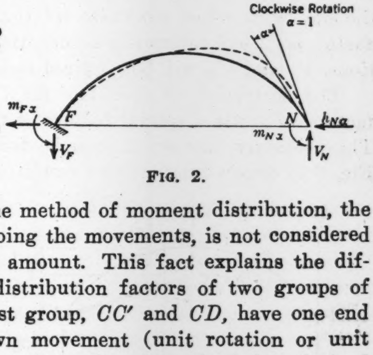

FIG. 2.

In the method of this paper unlike the method of moment distribution, the pier-head, *B,* adjacent to the one undergoing the movements, is not considered fixed, but is allowed to move its proper amount. This fact explains the difference in the method of determining distribution factors of two groups of members in Fig. 1. Members of the first group, *CC′* and *CD,* have one end fixed, the other end undergoing a known movement (unit rotation or unit translation). Their distribution factors will be found by formulas, derived subsequently. The other three members have unknown movements of one end, and their distribution factors will be found by means of a special algebraic process.

In concluding this brief outline it may be mentioned that the method suggested consists largely in following a certain simple arithmetical procedure, without recourse to higher mathematics. Formulas are used only in evaluating the end distribution factors of single members, and the constants involved are those commonly used in expressing the familiar elastic properties of arches and piers.

END DISTRIBUTION FACTORS OF SINGLE ARCHES AND PIERS

Rotation Factors of a Symmetrical Arch Rib.—Let *FN* (Fig. 2) be a single symmetrical span of a multiple arch. It is required to find expressions for the moments and thrusts at the ends, *N* and *F*, when *F* is kept fixed, and *N* is made to rotate, without any linear displacement, through an angle, $\alpha = 1$ radian, in positive direction (which will be assumed to be clockwise).

The end, *N*, which moves, will be referred to as the "near" end, and the fixed end, *F*, will be termed the "far" end. Then, the rotation thrust factor and the rotation moment factor at the near end will be designated, respectively, $h_{N\alpha}$ and $m_{N\alpha}$, and similar quantities at the end, *F*, will be denoted by $h_{F\alpha}$ and $m_{F\alpha}$.

A definite agreement as to the exact meaning and signs of these symbols is most important. In line with a common convention in the method of moment distribution, it will be assumed that *m* and *h* are the moments and thrusts with which the arch acts on the joint; and the positive directions for these actions will be clockwise for the moment, and to the right for the thrust.

Since each joint acts on the arch with forces equal and opposite to those with which the arch acts on the joint, a free-body diagram of the arch with Joint *N* rotated clockwise through an angle, $\alpha = 1$ radian, will appear as shown in Fig. 2. Directions for arrows, *m* and *h*, in this diagram are determined by the aforementioned convention concerning meaning and signs of the end distribution factors. The actual forces may have directions opposite the arrows shown, in which case the corresponding distribution factors will be found to be negative. Thus, it is quite evident that a clockwise moment is required at the end, *N*, to effect clockwise rotation of this end; consequently, the moment factor, $m_{N\alpha}$, will ultimately be negative. In addition to *m* and *h*, vertical reactions, V_N and V_F, will be required to keep the span in static equilibrium.

The derivation of formulas for the moment factors, *m*, and the thrust factors, *h*, is not a special feature of this paper, but is given for completeness. The necessary expressions can be found easily by the neutral point method. Fig. 3 is drawn for the same conditions of deformation as Fig. 2. The arch has a rigid arm extending from the end, *N*, to the neutral point, *O*, and is loaded at Point *O* with the forces, $h_{N\alpha}$, V_N, and M_O, which have been moved there from Point *N*. Since systems of forces in Figs. 2 and 3 are equivalent to each other, the following relation is evident from statics:

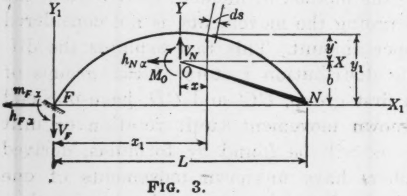

FIG. 3.

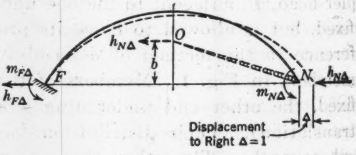

FIG. 4.

$$m_{N\alpha} = -\left[M_o + V_N \frac{L}{2} - h_{N\alpha}\, b \right] \ldots\ldots\ldots\ldots\ldots (1)$$

By assumption, the only movement at Point N is rotation through an angle, $\alpha = 1$ (see Fig. 2); consequently, a composite movement occurs at the neutral point, O, as follows: (1) Clockwise rotation, $\alpha = 1$; (2) vertical displacement, $\frac{L}{2}$, upward; and (3) a horizontal displacement, b, to the right, in which, b is the height of the neutral point above the springing line.

In order to effect these displacements, the forces must be exerted at Point O such as to satisfy the following conditions (derived from the well-known properties of the neutral point):

$$M_o \int \frac{ds}{EI} = 1 \text{ ....}(2)$$

$$V_N \int \frac{x^2\, ds}{EI} = \frac{L}{2} \text{ ....}(3)$$

and,

$$-h_{Na}\left[\int \frac{y^2\, ds}{EI} + \int \frac{ds}{EA}\right] = b \text{ ....}(4)$$

The unknowns, M_O, V_N, and h_{Na}, are easily found from these relations; and, then, m_{Na}, m_{Fa}, and h_{Fa} are determined from Equation (1), and from the conditions of equilibrium of the arch. The resultant expressions for the rotation distribution factors of a single arch are:

$$m_{Na} = -\left[\frac{1}{\int \frac{ds}{EI}} + \frac{\left(\frac{L}{2}\right)^2}{\int \frac{x^2\, ds}{EI}} + \frac{b^2}{\int \frac{y^2\, ds}{EI} + \int \frac{ds}{EA}}\right] \text{....}(5)$$

and,

$$m_{Fa} = \frac{1}{\int \frac{ds}{EI}} - \frac{\left(\frac{L}{2}\right)^2}{\int \frac{x^2\, ds}{EI}} + \frac{b^2}{\int \frac{y^2\, ds}{EI} + \int \frac{ds}{EA}} \text{ ....}(6)$$

and,

$$h_{Fa} = -\,h_{Na} = \frac{b}{\int \frac{y^2\, ds}{EI} + \int \frac{ds}{EA}} \text{.............}(7)$$

It should be pointed out that the axes of the co-ordinates, X and Y, to which values of x and y are referred in Equations (5), (6), and (7), pass through the neutral point, O (Fig. 3), and are directed horizontally and vertically. The distance, b, determining the location of the neutral point, is found from the relation:

$$b = \frac{\int \frac{y_1\, ds}{EI}}{\int \frac{ds}{EI}} \text{ ....}(8)$$

The following will be found useful in evaluating the integrals:

$$\int \frac{x^2\,ds}{EI} = \int \frac{x_1^2\,ds}{EI} - \left(\frac{L}{2}\right)^2 \int \frac{ds}{EI} \quad \text{(9)}$$

and,

$$\int \frac{y^2\,ds}{EI} = \int \frac{y_1^2\,ds}{EI} - b^2 \int \frac{ds}{EI} \quad \text{(10)}$$

In Equations (8), (9) and (10), x_1 and y_1 are co-ordinates of the arch axis referred to Axes X_1 and Y_1 with the origin, F, at the springing.

Displacement Factors of a Symmetrical Arch Rib.—Following the same convention as in the case of the rotation factors, the displacement factors are defined as the moments and horizontal thrusts with which the arch acts on the joints when the far end, F, remains fixed, and the near end, N, is displaced horizontally to the right (with no rotation) a distance of one unit of length (see Fig. 4). Positive directions for these actions of the arch on the joints (not of the joints on the arch) will be again assumed as to the right for thrusts, and clockwise for moments.

The movement of the neutral point under these circumstances will evidently be the same as that of the point, N, namely, one unit of length to the right; and this may be effected by a single horizontal force, $h_{N\Delta}$, applied at Point O, as shown by the broken line in Fig. 4, thus:

$$h_{N\Delta} = -\frac{1}{\int \frac{y^2\,ds}{EI} + \int \frac{ds}{EA}} \quad \text{(11)}$$

Expressions for the other factors will be found from the conditions of equilibrium:

$$h_{F\Delta} = -h_{N\Delta} \quad \text{(12)}$$

and,

$$m_{F\Delta} = -m_{N\Delta} = \frac{b}{\int \frac{y^2\,ds}{EI} + \int \frac{ds}{EA}} \quad \text{(13)}$$

Equations (5) to (13), inclusive, developed on the condition that the right end of the arch moves and the left end remains fixed, hold true in exactly the same form (and with the same signs) when the left end moves, and the right end stands still.

For investigating the influence of movements of the abutments, it is necessary to write expressions for terminal forces when one end of the arch settles vertically without rotation through a distance of one unit of length, and the other end remains fixed. It is easy to prove that no horizontal thrusts occur in this case, and that the end moments are equal to,

$$m_V = \frac{\frac{L}{2}}{\int \frac{x^2\,ds}{EI}} \quad \text{(14)}$$

the sign being plus on both ends if the right end of the arch moves down.

Rotation and Displacement Factors for a Pier with Fixed Base.—Fig 5 represents an elastic pier, fixed at the base, B, with a unit clockwise rotation at the top, T, with no linear displacement, and subjected to the action of the forces, $m_{T\alpha}$ and $h_{T\alpha}$ (reversed rotation factors for the pier). In Fig. 6 these forces have been moved as M_o and $h_{T\alpha}$ to the extremity of a rigid arm terminating at the neutral point of the pier, a distance, a, below its top. Evidently,

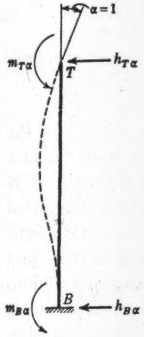

FIG. 5.

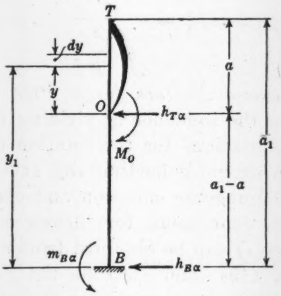

FIG. 6.

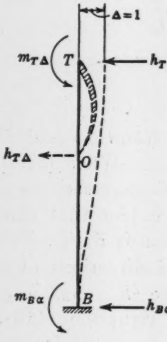

FIG. 7.

$$m_{T\alpha} = -\left[M_o + h_{T\alpha}\, a\right] \dots\dots\dots\dots\dots\dots (15)$$

The neutral point, O, has the following movements: Clockwise rotation, $\alpha = 1$, and linear displacement to the left, a. These are produced by,

$$h_{T\alpha} = \frac{a}{\int \frac{y^2\, dy}{E\, I}} \dots\dots\dots\dots\dots\dots (16)$$

and, $M_o = \dfrac{1}{\int \frac{dy}{E\, I}}$; then, from Equation (15),

$$m_{T\alpha} = -\left[\frac{1}{\int \frac{dy}{E\, I}} + \frac{a^2}{\int \frac{y^2\, dy}{E\, I}}\right] \dots\dots\dots\dots (17)$$

The y - co-ordinates of the pier axis, under the integral signs in Equations (16) and (17), are measured from the origin at the neutral point. In order to simplify the evaluation of the integrals, the following relation may be used:

$$\int \frac{y^2\, dy}{E\, I} = \int \frac{y_1^2\, dy_1}{E\, I} - (a_1 - a)^2 \int \frac{dy_1}{E\, I} \dots\dots\dots (18)$$

in which, y_1 and a_1 are measured from the base of the pier (see Fig. 6).

Similar argument leads to the following expressions for the displacement factors of a pier with fixed base (Fig. 7):

$$h_{T\Delta} = -\frac{1}{\displaystyle\int \frac{y^2\,dy}{E\,I}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

and,

$$m_{T\Delta} = \frac{a}{\displaystyle\int \frac{y^2\,dy}{E\,I}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

Rotation and Displacement Factors for a Pier That Can Move at the Base.—When investigating the influence of yielding foundations under a pier it is necessary to write expressions for the rotation and displacement factors of a pier that can rotate or move horizontally at the base, while the head remains fixed. Using the foregoing notation and convention as to the signs and directions of motions, expressions for thrusts and moments at the pier base ($h_{B\alpha}$, $m_{B\alpha}$, $h_{B\Delta}$, and $m_{B\Delta}$) can be obtained from corresponding expressions in Equations (16), (17), (19), and (20) at the pier-head by substituting $-(a_1 - a)$ for a. The force functions at the top of the pier, while the pier-head still remains locked, can then be found by statics.

NUMERICAL EXAMPLES

Application of this method will be demonstrated by two examples of arch systems with ribs and piers of the proportions used by Charles S. Whitney, M. Am. Soc. C. E., in his fundamental papers on arch design.[3] All ribs and piers (see Fig. 8) will be assumed to be 1 ft thick, and will have the properties listed in Table 1.[4]

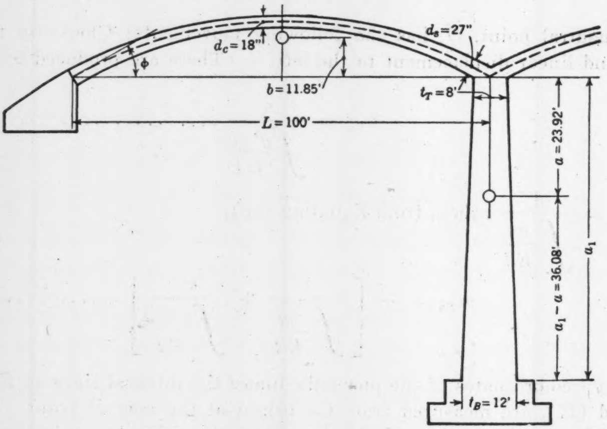

FIG. 8.

TABLE 1.—PROPERTIES OF RIBS AND PIERS IN NUMERICAL EXAMPLES (SEE FIG. 8)

Length of span, L, in inches	1 200
Rise of arch axis, r, in feet	15
Ratio, w, of unit loads, w_S, at springing to w_c, at crown	4.70
Ratio, n, of $\dfrac{I_c}{I_S \cos \phi}$	0.339
Coefficient, k, in $W = \cosh k$	1.5
Height of pier, a_1, in feet	60
Moment of inertia, I_T, of pier at the top $\left(= 1.1 \times \dfrac{8^3}{12}\right)$, in feet^4	46.85
Thickness of Arch Barrel, in Inches:	
(a) At the crown, d_c	18
(b) At the springing, d_S	27
Cosine ϕ	0.769
Distance, y_c, at the crown from the arch rib axis to the neutral point, in feet	3.15
Thickness of Pier, in Feet:	
(a) At the top, t_T	8.0
(b) At the bottom, t_B	12.0
Moment of Inertia of Arch Barrel, in Inches^4:	
(a) At the crown, I_c	6 399
(b) At the springing, I_s	24 560
Vertical distance, b, of neutral point above springing, in inches	142.2
Total height, $a_1 + b$, in feet	71.85
Distance, a, in inches (see Fig. 8)	287
Distance, $a_1 - a$, in inches (see Fig. 8)	433

The following values have been found from the formulas developed by Mr. Whitney:

For an Arch Rib:

$$E \int \frac{ds}{E\,I} = 0.1252 \text{ in.}^{-3} \quad \dots\dots\dots\dots\dots\dots (21)$$

$$E \int \frac{x^2\,ds}{E\,I} = 11\,354 \text{ in.}^{-1} \quad \dots\dots\dots\dots\dots\dots (22)$$

and,

$$E \int \frac{y^2\,ds}{E\,I} = 247.9 \text{ in.}^{-1} \quad \dots\dots\dots\dots\dots\dots (23)$$

For a Pier:

$$E \int \frac{dy}{E\,I} = 0.0004106 \text{ in.}^{-3} \quad \dots\dots\dots\dots\dots\dots (24)$$

and,

$$E \int \frac{y^2\,dy}{E\,I} = 16.7 \text{ in.}^{-1} \quad \dots\dots\dots\dots\dots\dots (25)$$

The influence of rib-shortening, expressed by the integral, $\int \frac{ds}{E A}$, is slight and will be disregarded in the following examples. Numerical values for the end distribution factors are obtained by substituting the quantities in Equations (21) to (25) in Expressions (5) to (20). The results are listed in Table 2, the factors being divided by E. For example, the rotation factor, h_{Fa}, in Table 2, is actually $\frac{h_{Fa}}{E}$.

It is easy to understand that the absolute values of distribution factors are not essential, and that quantities proportional to them will serve as well in distributing unbalanced joint moments and thrusts. Moreover, the coefficient of proportionality for rotation factors may be made different from that for the displacement factors. A change in this coefficient may be advisable in order to raise or to lower the values of the factors, thus avoiding the inconvenience of using numbers that are too large or too small.

In the following numerical examples, the quantities, $\frac{h_a}{E}$ and $\frac{m_a}{E}$, will be used as the rotation factors, and the quantities, $\frac{100\ h_\Delta}{E}$ and $\frac{100\ m_\Delta}{E}$, as the displacement factors, $\frac{1}{E}$ and $\frac{100}{E}$, being the coefficients of proportionality.

It is evident from the physical meaning of the distribution factors that: m_a is measured in force length units; h_a, in force units; m_Δ, in $\frac{\text{force length}}{\text{length}}$ units; and, h_Δ, in $\frac{\text{force}}{\text{length}}$ units.

TABLE 2.—END DISTRIBUTION FACTORS OF RIBS AND PIERS IN NUMERICAL EXAMPLES (DIVIDED BY E; SEE TABLE 1)

ROTATION FACTORS			DISPLACEMENT FACTORS		
Equation No.	Factor	Value	Equation No.	Factor	Value
(7)	h_{Fa}	0.574 in.^{2}	(12)	$h_{F\Delta}$	0.00404 in.
(7)	h_{Na}	—0.574 in.^{2}	(11)	$h_{N\Delta}$	—0.00404 in.
(5)	m_{Na}	—121.2 in.^{3} = — 10.1 in^2-ft.	(13)	$m_{N\Delta}$	—0.574 in.^{2} = — 0.0478 in-ft.
(6)	m_{Fa}	57.8 in.^{3} = 4.82 in^2–ft	(13)	$m_{F\Delta}$	0.574 in.^{2} = 0.0478 in-ft.
(16)	h_{Ta}	17.19 in.^{2}	(19)	$h_{T\Delta}$	—0.0599 in.
(17)	m_{Ta}	—7371 in.^{3} = — 614.2 in^2-ft.	(20)	$m_{T\Delta}$	17.19 in.^{2} = 1.433 in-ft.
(14)	m_e	0.0528 in^2 = 0.0044 in–ft	.....	......	....

The important feature is that the moment factors have length dimensions of a power one degree higher than that of the corresponding thrust factors. The same characteristic is preserved in the units of the proportional values (see Table 2). This extra length dimension (an exponent of 3 in m_{Na}, for example, as compared with 2 in h_{Na}) is different from the remaining dimensions, and although the others may be expressed either in inches or in feet, the units of this particular dimension must agree with the length units of the fixed-ended moments.

This is the reason for the seemingly peculiar combinations of inches and feet in the units of the moment factors in Table 2. These combinations evidently result from the fact that the fixed-ended moments are expressed in kip-feet. Of course, it would be quite correct, although inconvenient because of small values, to have the proportional distribution factors expressed in feet only. Aside from this single qualification, the units of distribution factors are quite immaterial, and may be disregarded completely, unless the absolute values of terminal deformations are considered, as in the case of yielding foundations.

Example 1.—Table 3 contains the complete solution of a 2-span arch. Moments are expressed in kip-feet, and thrusts, in kips. The ribs and piers have the dimensions and elastic properties listed in Tables 1 and 2. The structure is loaded to the middle of the left span, as shown in Fig. 9, with a uniform load of $w = 0.1$ kip per lin ft. Pier Base B' and the abutments, A and C, are considered as absolutely fixed.

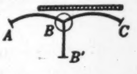

FIG. 9.—EXAMPLE 1.

TABLE 3.—END MOMENTS AND THRUSTS, TWO-SPAN ARCH BRIDGE (SEE FIG. 9)

(Thrusts, h, are in kips; and moments, m, are in kip-feet)

* Values of h are the same as in Column (3), with opposite signs. † Value of h are the same as in Column (7), with opposite signs.

The vertical columns in Table 3 contain moments and thrusts. The values refer to the ends of the various members, thus: Columns (3) and (4) (Table 3), headed "B_A", give forces at End B of Member BA, Fig. 9. Columns (9) and (10) contain the values of forces acting on Joint B. They are computed by adding, algebraically, the quantities of the three preceding columns, B_A, B_B', and B_C.

The conditions or causes that produce the forces are listed in Column (1), Table 3. Items Nos. 1 and 2 contain forces caused by the rotation, $\alpha = \dfrac{1}{E}$, and the displacement, $\Delta = \dfrac{100}{E}$, of Joint B; for this reason, Joint B is shown in a circle in Fig. 9; in other words, the quantities listed in these two items are the distribution factors for movements of Joint B.

Item No. 3, Table 3, contains the fixed-ended forces of the two single spans under the action of given uniform load. These values have been computed by means of diagrams and formulas given in the paper by Mr. Whitney, previously cited. If there was any known movement of the supports its influence would be calculated by Equations (5) to (20), and included with the fixed-ended forces from the load.

It follows from Item No. 3, Table 3, that there are at Joint *B*, an unbalanced thrust of $-$ 4.482 kips and an unbalanced moment of $-$ 25.02 kip-ft, which cause this joint to rotate through an unknown angle, α, and to move horizontally an unknown distance, Δ, so that the forces at this joint become balanced. If the rotation, α, is measured in angular units containing $\frac{1}{E}$ radians, and the displacement, Δ, in linear units of the magnitude, $\frac{100}{E}$, the numerical values of these unknowns are found from the equations of equilibrium of the joint, B: $\Sigma H_B = 0$ and $\Sigma M_B = 0$, which give:

$$h_\alpha \alpha + h_\Delta \Delta + h_{B\,(fixed)} = 0 \text{..................} (26)$$

and,

$$m_\alpha \alpha + m_\Delta \Delta + m_{B\,(fixed)} = 0 \text{..................} (27)$$

Substituting values of *h* and *m* (Joint *B*) from Items Nos. 1, 2, and 3, Table 3, Equations (26) and (27) become, respectively:

$$16.04\ \alpha - 6.80\ \Delta - 4.482 = 0 \text{................} (28)$$

and,

$$-\ 634.4\ \alpha + 133.7\ \Delta - 25.02 = 0 \text{................} (29)$$

in which the coefficients before the α and Δ - terms are the distribution factors of Joint *B*. From Equations (28) and (29): $\alpha = -\ 0.3541$; and, $\Delta = -\ 1.494$.

Items Nos. 4 and 5, Table 3, give forces caused by the rotation, $0.3541\,\frac{1}{E}$, and the displacement, $1.494\,\frac{100}{E}$, of Joint *B*. Item No. 6 is obtained by adding, algebraically, Items Nos. 3, 4, and 5, and gives the total terminal moments and thrusts in various members of the structure under the loading considered.

In Item No. 6, values of *h* in Columns (3), (5), and (7), and values of *m* in Columns (4), (6), and (8), should add to zero. This constitutes a good check on the solution of the equations. A small discrepancy found as a result of this check has been thrown into the pier, the rigidity and distribution factors of which exceed, greatly, the corresponding values for the other members of this joint. The amounts of rotation and translation of Joint *B* under the action of unbalanced forces can also be found graphically. The graphical solution, however, will not be given in this paper.

Example 2.—A 4-span arch is analyzed in this more difficult example (see Fig. 10). The arch ribs and piers are alike and have the same dimensions and elastic properties as those in Example 1 (see Tables 2 and 3). The abutments and pier bases are again considered as absolutely fixed.

FIG. 10.—EXAMPLE 2.

Several methods of procedure can be adopted, the simplest one being, perhaps, to consider the structure as a combination of two 2-span arches, *ABC* and *CDE*, with Joint *C* fixed; and then to unlock this joint and to introduce the influence of its movements. This procedure necessitates, first, the determination of distribution factors for the movements of Joint *C*, which differ from those given by Equations (5) to (13), because the structure is extended two spans from Joint *C* instead of one.

Fig. 11 is arranged on the same basis as Table 3; the diagrams of structures in Column (2) being inserted to assist in forming mental pictures of the various steps taken, before the final solution is reached. As is evident from the diagrams, the necessary characteristics of the 4-span arch are determined after a preliminary study of 1-span and 2-span arches. The joint undergoing movement at each step is indicated by a circle around it on the diagram.

Fig. 11, Items Nos. 1 and 2, contains the already familiar distribution factors of a 2-span arch, *ABC*, with Points *A*, *B'*, and *C* fixed and Point *B* (in a circle) free to move. Item No. 3 gives rotation factors for a single arch, *BC*, when Joint *B* is fixed, and Joint *C* is permitted to move. Of course, these quantities are the same as those in Item No. 1, Columns (3), (4), and (5).

If Joint *B*, acted upon by forces in Item No. 3, is unlocked, it rotates and moves horizontally, as a center joint of a 2-span arch, so that the forces become balanced. These movements are found from formulas similar to Equations (26) and (27) by substituting the proper thrust and moment factors from Fig. 11, thus:

$$16.04\,\alpha - 6.80\,\Delta + 0.574 = 0 \quad\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

and,

$$-\,634.4\,\alpha + 133.7\,\Delta + 4.82 = 0 \quad\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

For clearness, Equations (30) and (31) are stated also in Fig. 11. From these equations, $\alpha = 0.0505$; and, $\Delta = 0.2035$.

The effect of these movements is expressed by the forces calculated in Items Nos. 4 and 5. When these values are added to the original forces in Arch *BC* before Joint *B* has moved (Item No. 3), the result is the final forces (Item No. 9), in various members of the double-span arch, *ABC*, when Joint *C* undergoes the specified pure rotation, $\frac{1}{E}$, and Joint *B* moves in a manner suitable to the occasion. In other words, Item No. 9 contains rotation distribution factors of the 4-span arch corresponding to movements of the center joint, *C*. The displacement factors are found similarly in Items Nos. 6, 7, 8, and 10, Fig. 11.

SPAN ARCH UNDER UNIFORM LOAD, $w = 0.1$ KIP PER FOOT.

Items Nos. 9 and 10, Fig. 11, are completed by filling Columns C_C and C_D, and by adding, algebraically, the three *C*-columns to find the joint distribution factors. There is no need to fill in the various *D* and *E*–columns, since their factors are identical with those of the symmetrically opposite members, *B* and *A*. This concludes the first stage, preliminary to investigation of four cases of loading. For clearness, it may be re-emphasized that this first stage has resulted in the determination of:

(1) Terminal forces in the 2-span arch, *ABC,* caused by unit rotation and unit translation of Joint *B* (Items Nos. 1 and 2, Fig. 11).

(2) Terminal forces in the 4-span arch, *ABCDE,* caused by unit rotation and unit translation of Joint *C* at the center (Items Nos. 9 and 10, Fig. 11).

Item No. 11 contains the fixed-ended forces of a single arch, *BC,* under a uniform load (Case 1), on the right half of Span *BC*. Item No. 14, the sum of Items Nos. 11, 12, and 13, gives the terminal forces of the double-span arch, *ABC,* under the same loading, after the unbalanced forces at Joint *B* have been distributed, using factors in Items Nos. 1 and 2 and solving the equations given on the right side of Fig. 11 opposite Item No. 11. The only remaining step is to distribute the unbalanced forces at Joint *C*, using the distribution factors in Items Nos. 9 and 10. The following equations of the form of Equations (26) and (27) are used:

$$16.26\,\alpha - 6.63\,\Delta + 3.675 = 0 \qquad (32)$$

and,

$$-\,632.00\,\alpha + 135.60\,\Delta - 21.26 = 0 \qquad (33)$$

from which the movements of the joint, *C*, are found to be: $\alpha = 0.1800\,\frac{1}{E}$ and $\Delta = 0.9956\,\frac{100}{E}$. The effects of movements of the joint, *C*, on the members in various *D* and *E*–columns are the same as on the members symmetrically located on the left side of the structure. The resultant terminal forces are entered in Item No. 17.

Case 2, in which a uniform load occupies the left half of Span *BC*, is investigated and the results are entered as Items Nos. 18 to 24, Fig. 11. Only two distributions of unbalanced forces are needed for its solution, since distribution factors of Joint *C* are already known. The equations used are all stated in Fig. 11.

It is interesting to notice that only one distribution is required for either Case 3 or Case 4, since their 2-span values can be written down directly by comparison with Cases 2 and 1. Investigation of all four cases thus requires less than twice the work on one case.

General Case of a Structure with Any Number of Spans.—Example 2 presents a good illustration of the use of the method, not only for a 4-span arch, but also for a series with any number of spans. Probably, the best procedure is to divide the structure into two parts by fixing a joint at the center (or near the center for an odd number of spans), to analyze each part separately, and then, having determined distribution factors for movement of the temporarily fixed joint, to distribute the unbalanced forces at that joint.

After the preliminary work of calculating distribution factors, the necessary distributions for the load require relatively little time. In designing a multiple arch there are several cases of loading under which the structure should be investigated, and when using this method, the more cases are analyzed the less work on the average is involved in each, as has been already demonstrated in connection with Example 2.

The method can also be applied to the construction of influence lines. An influence line for moment or thrust at any point can be found by the use of Maxwell's reciprocal theorem, as a deflection curve of a suitably deformed structure after the unbalanced terminal forces caused by the deformation have been distributed in the usual manner. This procedure is cumbersome, because it requires the translation of moments into deflections.

However, a complete set of influence lines of all terminal forces (and this is what is generally required in the final analysis of the structure, if influence lines are used at all) can be found comparatively easily, following closely the procedure of Example 2, by placing a unit load, successively, at different points of the arch. In Example 2 this method requires only twenty-seven distributions to construct influence lines for all ten terminal forces, having ordinates at the tenth-points of the spans. This amount of work is not unreasonable in view of the great number of force functions.

Alternative Method.—In cases requiring a large number of distributions, a change in the procedure is recommended which does away with the equations determining the necessary movements of the joints. This modified procedure is presented, as applied to Case 1 under the sub-title, "Alternative Method," in Fig. 11. The idea is to replace the rotation and displacement factors with, what may be termed, *m*-factors and *h*-factors. There are again four of these factors at each end of each member: (1) The *m*-moment factor, m_m; (2) the *m*-thrust factor, h_m; (3) the *h*-moment factor, m_h; and (4) the *h*-thrust factor, h_h.

The first two are, respectively, the moment and the thrust that occur at the end of any member (as, for example, A_B), when the joint under consideration (say, B) is acted upon by a moment of 1, or 100, created by some external agency. As a result of this moment, Joint B undergoes both rotation, α, and horizontal translation, Δ, the values of which can be found easily, and from these movements the moments and thrusts at the ends of all members (the *m*-factors) can be computed. Similarly, the *h*-factors are the moments and thrusts at different terminals when the joint in question is acted upon by a thrust, $h = 1$.

The *m*-factors and *h*-factors for a 2-span arch, *ABC*, with movement at Joint B are determined in Items Nos. 33 to 38, Fig. 11, by the use of rotation and displacement factors in Items Nos. 1 and 2. Equations necessary for finding the movements of Joint B, when it is acted upon by a moment, 100, are as follows:

$$16.04\,\alpha - 6.80\,\Delta = 0 \quad (34)$$

and,

$$-\,634.40\,\alpha + 133.70\,\Delta + 100.00 = 0 \quad (35)$$

whence $\alpha = 0.313$ and $\Delta = 0.739$.

Forces caused by these movements are added in Item No. 37, Fig. 11, which thus presents the *m*-factors of the 2-span arch, *ABC*. The *h*-factors, found in a similar manner, are recorded in Item No. 38. Items Nos. 43 and 44, Fig. 11, contain the *m*-factors and *h*-factors for a 4-span arch with motion at the center joint, *C*; they are found by following a similar procedure.

These four additional distributions involved in determining *m*-factors and *h*-factors eliminate the equations when investigating the influence of unbalanced fixed-ended forces. Thus, in the 2-span arch, *ABC*, under the loading of Case 1 (Items Nos. 45 to 48, Fig. 11), the influence of the fixed-ended thrust, − 4.482 kips, at Joint *B*, is found at Item No. 47 as a product of this quantity and the corresponding *h*-factors, without resort to equations. The same is true with regard to the unbalanced moment, − 25.02 kip-ft.

CONCLUSIONS

The following conclusions are advanced as to the value and limitations of the method presented in this paper:

(1) With the exception of evaluation of distribution factors for single members (which is not considered a requisite part of this analysis), the method does not involve mathematics higher than elementary algebra.

(2) The idea behind the method is simple, and the various steps in the solution are quite easy to visualize, especially when accompanied by small supplementary diagrams.

(3) The nature of the computations, involving multiplication of a string of numbers by a single factor, makes the method particularly suitable for slide-rule work. (All computations in Table 3 and Fig. 11 have been made with an ordinary 10-in. slide-rule.)

(4) The orderly tabulation diminishes a possibility of errors.

(5) The algebraic sum of the terminal forces for three members meeting at a joint must equal zero. This provides an effective check on the results, the only exception being the moments at the abutments. In fact, there is little chance for mistake, after the fixed-ended forces and the single-span distribution factors have been determined correctly.

(6) Perhaps the part of the method most likely to cause confusion is the convention pertaining to the meaning and signs of distribution factors. The signs of some of the single-member distribution factors, when observed casually (see Items Nos. 1 and 2, Fig. 11), may seem quite odd. However, once the convention is mastered, and one visualizes the movement of the end of the member in relation to its neutral point, a good reason becomes apparent for each sign.

(7) The examples solved have dealt with a series of equal symmetrical arches, but there is no change when individual arches are different but sym-

metrical. The method still applies to asymmetrical arches, although Expressions (1) to (14), for distribution factors, are no longer valid.

(8) Vertical settlement of the joints due to pier-shortening has been disregarded; it is not important, but can be taken care of independently afterward, if desired. With the exception of this theoretical limitation, the method is "exact" in a sense that it is not based on assumptions other than the ordinary ones of the theory of elasticity.

(9) While, perhaps, this method may prove more laborious than some others when investigating one load condition, the writer believes that time will be saved when applying it to several load conditions, or to the construction of influence lines. It may be mentioned in this connection that a casual inspection of Fig. 11 is likely to convey an exaggerated idea of the labor involved in the solution. The fact is that many of the values are merely copied from one column into another, and any one acquainted with the procedure will find simplifications and "short-cuts" that will lessen the work.

ACKNOWLEDGMENT

The writer wishes to acknowledge his indebtedness to A. H. Finlay, Assoc. M. Am. Soc. C. E., for reading the manuscript and for most valuable criticism and suggestions.

DISCUSSION

L. E. GRINTER,[5] ASSOC. M. AM. SOC. C. E. (by letter).—Another exposition of the application of the Cross method of moment distribution to the analysis of multiple arches, is contained in this paper. The first was a discussion[6] of Professor Cross' paper on the "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Donald E. Larson, Jun. Am. Soc. C. E. Mr. Hrennikoff's presentation is highly satisfactory and should be read widely by those who have become familiar with the Cross method.

The extension of the conception of balancing moments and shears to the complex problem of the analysis of a series of arches on elastic piers has intrigued the interest of numerous investigators. The writer made his own extension in 1927 and has taught the theory of multiple-arch analysis by the general method of successive corrections[7] to his graduate students since 1929. It is interesting that the general method of successive corrections, devised to apply to any frame in which joint translation occurs, becomes essentially the same as the method described by Mr. Hrennikoff when it is applied to a multiple-arch system.

It is perhaps unfortunate that the author does not generalize his method of attack and explain its wide application, for the reader is more than likely to gain the impression that the paper deals with a group of special devices, of use only in the analysis of multiple arches. The simple explanation that follows makes the method generally applicable to all multiple-bay or multiple-story structures:

1.—With joints fixed against both rotation and translation, determine the fixed-end moments and the reactions at the ends of each loaded span.

2.—Balance moments with joints held against translation and determine the changes in the restraining forces that exist at the joints.

3.—Eliminate all artificial joint forces by permitting the joints to translate without rotation under the action of an equal and opposite set of forces. Determine the new set of fixed-end moments introduced by this translation.

4.—Repeat Steps 2 and 3 as many times as necessary (seldom more than twice) to reduce the unbalanced moments and artificial joint forces to negligibly small factors.

The importance of placing emphasis upon these simple steps is that they attach a physical significance to the procedure which is so likely to be obscured when use is made of a table, such as Fig. 11. The method of successive corrections can be arranged into a mechanical procedure, but it is doubtful whether any important advantage is obtained. Of course, an orderly arrangement of calculations will reduce the labor of analysis and the probability of error; but over-standardization will make any procedure so highly mechanical that the various steps lose their physical significance and the method is then likely to become unintelligible to most readers. The primary reason why the Cross method has become widely popular is that each step of the procedure has a physical significance, and there is no reason why the general method of successive corrections should not retain this important characteristic.

[6] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 127.

[7] *Loc. cit.*, p. 18; and Vol. 98 (1934), p. 611.

The only difficulty experienced by the writer's students in the use of this method for continuous arch analysis has been in regard to the signs of the thrusts at the tops of the piers. This difficulty is largely eliminated by the use of arrows to indicate the direction of thrust, instead of the conventional signs. The suggestion is in line with the desire to maintain the greatest possible physical significance for each step of the process. The convention that a positive bending moment at the end of a member tends to rotate the adjacent joint clockwise has been found most satisfactory.

The detailed procedure by which the constants for moment or thrust distribution are obtained, is of no great importance. Mr. Hrennikoff seems to prefer formularization by means of the neutral point conception, whereas the writer would commonly choose the simple direct application of the column analogy.[8] A knowledge of the column analogy for obtaining distribution constants and a full understanding of the four listed steps of successive corrections make totally unnecessary the remembrance of any special terminology or special devices for the analysis of continuous arch systems.

The determination of influence lines for multiple arches is reasonably simple if the shape of the deflected load line corresponding to the proper unit displacement is found by the aid of the conjugate-beam theory. In this case it is particularly convenient to produce the proper unit distortions, successively, by the use of the column analogy. There is no particular reason for choosing between the determination of influence lines for arch forces or pier reactions. In either case one must obtain three key influence lines for each span after which these may be combined by statics to obtain any influence line desired.

The writer is hopeful that Mr. Hrennikoff's paper may help to convince designers that the proper analysis and design of a system of continuous arches is no longer an impossibly difficult task, or, for that matter, not even a particularly tedious task. Certainly, there is no real justification for neglecting the elastic properties of a pier when such neglect might conceivably endanger the structure. Much "water has passed under the bridge" in the last few years in regard to the theory of structures, and this paper is clearly indicative of the changes that are taking place.

N. M. NEWMARK,[9] JUN. AM. SOC. C. E. (by letter).—A method of analyzing multiple arches is presented in this paper which Mr. Hrennikoff states "is based on the well-known principle of moment distribution." A discussion of similar methods that have appeared in previous American literature may be of some interest.

[8] "The Column Analogy," by Hardy Cross, M. Am. Soc. C. E., *Bulletin No. 215*, Univ. of Illinois, Eng. Experiment Station, Urbana, Ill.

[9] Research Asst. in Civ. Eng., Univ. of Illinois, Urbana, Ill.

It appears that the author's analysis of multiple-span arches is based upon a solution for the movements of the pier tops due to a given loading. These movements are then converted to forces and moments in the spans and piers. The method is similar, therefore, to the slope deflection method. Equations may be written for the forces (moments, thrusts, and shears) at the end of a member, either arched or straight, in terms of the displacements of that end, and of the far end, of the member.[10] Summing the forces at a joint (for all the members meeting at that point) in terms of the displacements and equating this sum to the unbalanced force at that joint yields a group of relations between the unbalanced forces and the joint displacements necessary to balance these forces. These are the equations used by Mr. Hrennikoff. When only two arch spans and a pier are considered (the far ends of the arch spans being fixed and vertical deflection of the pier being neglected), there are only two degrees of freedom of movement of the joint; hence, there are two unknowns and two equations to solve. When the displacements are found, the forces may be determined directly. When there are more spans, each equation will contain more unknowns, but the work of solution may be performed in the manner indicated by the author.

The general case has been treated by Mr. A. P. Hjort[11] who solves the equations by successive elimination of the unknowns, which is rather a tedious process when the number of unknowns is large; but for some types of structure, the coefficients of the unknowns are such that an accurate solution is possible without unwarranted precision in intermediate computations.

Professor Cross has suggested that these equations may be solved by successive convergence or successive approximations.[12] In an unpublished thesis submitted to the University of Illinois in partial fulfillment of the requirements for the degree of Master of Science in 1930, D. E. Larson, Jun. Am. Soc. C. E., solved the equations in the manner suggested by Professor Cross.

Certain tricks facilitate the solution of the equations, and the author's paper demonstrates some of these tricks.

The concept of moment distribution and force distribution lends itself readily to the solution of this problem. The distribution of a moment at a given joint amounts to allowing that joint to rotate until the sum of the moments in the members meeting at the joint is equal to the unbalanced moment that existed before rotation. Thus, in the two-span, single-pier, arch system the unbalanced moment and the horizontal force at the pier top, due to any loading on the arches or piers, can be distributed by a rotation and a translation of the pier top. It will be found, however, that in general such a rotation balancing the moment, will introduce an unbalanced thrust at the pier top. Furthermore, a horizontal movement of the top of the pier balancing the thrust, will introduce an unbalanced moment at that point.

[12] "Statically Indeterminate Structures," by Hardy Cross, pp. 115–118, 1926.

However, the joints may be balanced successively until convergence in some particular cases where convergence does obtain; for example, see the discussion by Mr. Larson[13] of Professor Cross' paper on moment distribution.

The foregoing explanation may be extended, of course, to a multiple-span structure and, in terms of the moment distribution concept, moments and thrusts may be distributed at all the joints and carried over; then at each joint the thrust due to the moment distribution and the moment due to the thrust distribution are added to the carry-over moments and thrusts to obtain the new unbalanced moments and thrusts at that joint. In a number of cases, however, the unbalanced moments and thrusts are almost as great as the original forces, and convergence may be very slow. It is possible to obtain more rapid convergence by use of a procedure such as that given by the author when a movement of the pier top is found to balance both moment and thrust at the given joint.

Mr. Hrennikoff does not use the procedure of carry-over and redistribution, but prefers to take into account the actual degree of fixation of the far end of the members. However, for the example which he gives, the convergence will be so rapid that it is scarcely necessary to go through the exact computations. Note that in the author's method two equations in two unknowns must be solved to distribute the forces at each joint.

Professor Cross has recommended[14] a moment-distribution procedure to be used for arches on elastic piers which eliminates the solution of simultaneous equations. If, instead of distributing moments and forces at the joint, these are distributed at a point away from the joint so located that a unit rotation of this point will produce no unbalanced thrust at the point and a unit translation of the point will produce no unbalanced moment at the point, then moments and forces can be distributed directly. It might be noted that this is equivalent to solving the two equations in two unknowns of Mr. Hrennikoff's method by substituting for them two equations which contain one unknown each and hence may be solved directly. Mr. Hrennikoff's equations might have been set up in terms of the "neutral point" with this simplification. Note that the neutral point will change in position if the far ends of the members are not considered fixed. Professor Cross proposes carrying over the changes in thrust along certain thrust lines in the different members to shorten the computations.

The essential difference, then, between Professor Cross' method[15] and that of Mr. Hrennikoff is the use of the neutral point and of successive convergence for solving the equations.

The rapid convergence of the Cross procedure is surprising. The writer has had occasion to use it in the analysis of a number of three-span arches on elastic piers. In this problem, when the structure happened to be symmetrical, considerable simplification was possible; by using the scheme of symmetry and anti-symmetry no carry-overs were necessary and all distributions were made directly.

[13] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 127.

[14] *Loc cit.*, pp. 152–154.

[15] For formulas for the location of the neutral point and for the distribution and carry-over factors, as well as a complete description of the moment-distribution concept applied to multiple-arch analysis, see "Continuous Frames of Reinforced Concrete," by Hardy Cross and N. D. Morgan, Members, Am. Soc. C. E., pp. 316–330, 1932.

It is gratifying to note the distinction the author makes between analysis and design. So far as design is concerned refinements in analysis are not warranted. It is almost impossible to determine accurately the stresses in a multiple-span structure, because of the variation in elastic properties of the different spans and between different parts of each span. Furthermore, the results are always complicated by the effect of the superstructure. The elastic constants for arch spans may be modified as much as 100%, or even more, by the effect of the deck.

It is worse than futile to compute influence lines for a multiple-span arch neglecting the effect of the deck. It is possible, of course, to compute such influence lines for total moment, thrust, or shear at a section through both rib and deck when, by some means or other, fixed-end influence lines and elastic constants for the composite structure are obtained.

T. Y. Lin,[16] Jun. Am. Soc. C. E. (by letter).—The principle of moment distribution has been applied to the analysis of multiple arches in many ways, but the procedure suggested herein is among the very simplest.

It would probably be better to use the "kip-inch" unit instead of the "kip-foot" unit for the fixed-end moments. Not only will this eliminate much confusion and misunderstanding, but it will enable the application of the reciprocal theorem[17] to check many of the calculated values. For example, in Fig. 11, Items Nos. 1 and 2, in the column headed "B_A", applying that theorem, it is known that h due to $\alpha = \frac{1}{E}$ must equal m due to $\Delta = \frac{1}{E}$, and, therefore, $-0.574 = -4.78 \times 12 \div 100$. The same is true in the column headed "B_B", and the column headed "Joint B".

For Items Nos. 9 and 10, in the column headed "C_B": $-0.463 = -3.85 \times 12 \div 100$. Furthermore, in the column headed "Joint C": $16.26 = 135.6 \div 100$. For Items Nos. 40 and 41, in the column headed "Conditions", Δ due to $m = 1$ must equal α due to $h = 1$ and, therefore, $0.819 \div 12 = 0.0683$. Evidently, when more joints are considered, more such checks will be available.

A. H. Finlay,[18] Assoc. M. Am. Soc. C. E. (by letter).—The problem of analyzing multiple arches on elastic piers is one in which structural engineers are evidencing an increasing interest and Mr. Hrennikoff's paper, presenting as it does a novel and very direct method of analysis, is happily timed. The author's method presents a nice blending of two points of view. Starting with the basic idea of distribution factors and fixed-ended force functions he finds, in a simple and original manner, the joint movements necessary for equilibrium and, from these movements, the force functions to be combined with the original ones in order to get the final values.

[16] With Ministry of Railways, Chinese National Govt., Nanking, China.

[17] "Elastic Arch Bridges", by McCullough and Thayer, pp. 271 and 306.

[18] Asst. Prof. of Civ. Eng., Univ. of British Columbia, Vancouver, B. C., Canada.

Professor Cross has presented[19] a most ingenious solution of this problem, using his principle of force distribution in its most general form throughout. A description of this process will be of assistance in appraising the value of Mr. Hrennikoff's solution. For convenience of reference, the structure, symbolism, and sign conventions in this discussion are the same as those chosen by Mr. Hrennikoff.

If unbalanced force functions (that is, thrust and moment) are distributed in the usual manner many cycles will be necessary before a suitable balance is obtained. This is due, in part, to the fact that when, say, Joint *B* (Fig. 12), with adjacent joints locked, is translated horizontally without permitting rotation (in order to distribute horizontal thrusts), the thrusts ($h_{N\Delta}$ and $h_{T\Delta}$) produced in each adjoining arch and the pier by the moment, will produce in general, an unbalanced moment at Joint *B*. In other words during the translation the joint will have to be held against rotation. Similarly, when the joint is rotated without permitting translation (as when distributing moments) the horizontal components ($h_{N\alpha}$ and $h_{T\alpha}$) of the thrusts produced in each adjoining arch and the pier (Fig. 13) by the movement will produce, in general, an unbalanced thrust at Joint *B*. In other words, during the rotation of the joint it will have to be held against translation.

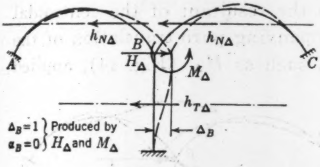

FIG. 12.

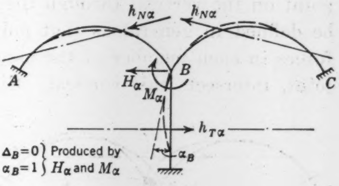

FIG. 13.

The lines of action and the magnitudes of the forces shown in Figs. 12 and 13 may be found in many ways. For convenience of comparison with the author's paper his h_Δ-forces evidently act along the thrust lines of Fig. 12 and his h_α-forces evidently represent the horizontal components of the forces acting along the thrust lines in Fig. 13, each of which passes through the neutral point of its respective member. The thrust lines in Fig. 13 are best located perhaps by finding their vertical distances from Points *A* and *B*. To facilitate comparison these distances, in the author's terminology, are, respectively, $\frac{m_{F\alpha}}{h_{F\alpha}}$, $\frac{m_{N\alpha}}{h_{N\alpha}}$, for an arch, and $\frac{m_{T\alpha}}{h_{T\alpha}}$ for the pier.

The foregoing comments have been intended to emphasize two points: First, the nature of the forces set up in each member of the assembly by each movement of the joint; and, second, the annoying unbalancing of one set of force functions caused by distributing the other set, which is inevitably associated with any distribution of force functions as long as such distribution is effected by pure translation and pure rotation of the joints themselves.

---

[19] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 152 *et seq.*; and "Continuous Frames of Reinforced Concrete," by Messrs. Cross and Morgan, p. 316 *et seq.*

Such a method of distribution, of course, will eventually produce a solution, and an interesting example of such a solution has been presented by Donald E. Larson, Jun. Am. Soc. C. E.[20]

Professor Cross has discussed this difficulty of slow convergence and has suggested how, in large measure, it may be avoided. He distributes force functions by pure translation and pure rotation of a point so chosen that it translates only under the action of a suitably directed force applied to the point and rotates only under the action of a couple applied to the point. He well styles this point the neutral point of the joint. In all cases this is a point on the vertical through the joint if the pier be incompressible. It may be defined in general as that point in which the resultant of the centroidal forces in each member of the assembly, accompanying pure translation of the joint, intersects this vertical. Since a force, such as H_{Δ} (Fig. 14), applied at this point causes only translation, the reciprocal theorem (of which that of Maxwell is a special case) shows that a couple, such as M'_{α} (Fig. 15), applied at the same point will cause it to rotate only.

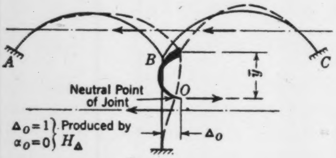

Fig. 14.

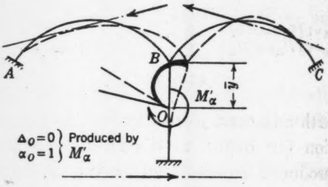

Fig. 15.

It will be interesting to note the lines of action of the forces produced in each member of the assembly by pure rotation and pure translation of such a point. These lines are shown in Figs. 14 and 15. As before, the magnitudes of the various forces can be found in different ways. One way is by considering the deflection of the neutral point of each member accompanying each specified movement of the point, *O*, and from these known deflections the forces accompanying them may be computed. For purposes of comparison it may be noted that the forces set up in the arches and pier in Fig. 14 are the same, of course, as those in Fig. 12 whereas, in Fig. 15, since the joint, *B*, has moved a distance, $\bar{y}$, to the right and has rotated through a unit angle, the forces set up are those in Fig. 13 plus $\bar{y}$ times those in Fig. 12. These relations are of no special interest, of course, except as they afford a convenient means, in this specific example, of checking numerical quantities used against those given by the author.

The distribution and carry-over factors may be found from the forces shown in Fig. 14 and Fig. 15, but it is more convenient to find them directly from consideration of the forces produced in each member of the assembly by a unit force and a unit couple, respectively, applied to the point, *O*. For the structure under consideration these forces are shown in Figs. 16 and 17.

---

[20] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 127.

The magnitudes of the horizontal components of the thrusts are written on their lines of action. Since the sign conventions follow those of the author the forces considered are those which the members exert on their terminal points. Positive directions are to the right for thrust and clockwise for moment. In both diagrams, therefore, Arch *A*-*B* is pulling to the left on Point *B* and to the right on Point *A*.

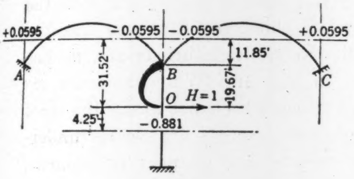

FIG. 16.

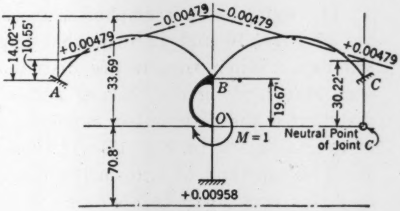

FIG. 17.

Distribution factors at Point *O* for thrust are -5.95% for each arch and -88.1% for the pier. Carry-over factors for thrust are evidently equal to the foregoing values and, for equilibrium, of opposite sign. Distribution factors for moment at Point *O* are, evidently, $-0.00479\ (33.69)\ 100 = -16.1\%$ for each arch and $0.00958\ (-70.8)\ 100 = -67.8\%$ for the pier. The carry-over factors for moment may be obtained in the same manner by multiplying the thrust by its appropriate lever arm, or they may be found from the distribution factors by multiplying by the appropriate ratio of distances. For example, the part of any unbalanced moment at Point *O* that is carried over to the neutral point of an adjacent joint, such as Point *C*, is $+16.1\,\dfrac{(30.22)}{(33.69)} = +14.5$ per cent. The plus sign merely means that, in this example, the carried-over thrust due to rotation is exerting a clockwise moment on the neutral point of Joint *C*. Summarized briefly, the foregoing means that unbalanced force functions at the neutral point of any joint are distributed among the members at such a joint with signs opposite to that of the unbalanced force function while they are carried over to the neutral points of adjacent joints with signs the same as that of the original unbalanced force function.

It should be realized clearly that, when distributing unbalanced thrusts by translating the neutral point, the distributed thrusts will cause no unbalanced moment at the neutral point. This follows, of course, from the definition of the neutral point, but a clear physical picture of this phenomenon can be obtained by realizing that the moments of the arch and pier thrusts in Fig. 14, or in Fig. 16 must balance about the neutral point of the joint. Similarly, when distributing moments by rotation of the neutral point, the distributed moments in the arches and pier will cause no translation of that point; that is, the horizontal components of the thrusts in the arches and pier accompanying such distribution must total zero as may be seen in Fig. 15, or in Fig. 17. This is the central idea in Professor Cross' ingenious method of distributing force functions. It follows from this that, during the actual distributing, no account need be kept of distributed functions but only of those parts of the unbalanced functions which are carried over to the neutral points of adjacent joints, since it is only these latter quantities that can unbalance any previously balanced neutral point.

The writer cannot emphasize too strongly the need of visualizing with the aid of Figs. 16 and 17 just what happens when the force functions are distributed. When thrusts are distributed, the distributed thrusts act, as has been stated, along the lines of action shown in Fig. 16. When moments are distributed the distributed moments set up thrusts which act along the lines of action shown in Fig. 17. If these two physical aspects are clearly understood the method of translating changes in thrusts into changes in moment, and *vice versa,* will be obvious.

Fig. 18 contains the full solution of all terminal forces for one load position. It should be noted that about one-half the tabular matter is devoted to the distribution proper, the remainder being given over to the tiresome but necessary translation of the various changes in thrust into final thrusts and moments. This latter is only simple arithmetic combined with the laws of statics, but, of course, it must be done. It is in this last step of the work that the distributed thrusts which, heretofore, have been ignored, enter the calculations. Since these distributed thrusts are equal numerically and opposite in sign to their respective carried-over thrusts they may be written by inspection. The end arches and the piers need not appear in the original distribution. This reduces the work materially but, of course, eliminates any check of the arithmetic by statics.

If many loading conditions are to be investigated the part of the work devoted to distribution can be reduced materially (as Professor Cross has demonstrated) by first distributing a unit horizontal force and a unit couple at each neutral point, beginning near the center of the structure. In this way a set of distribution factors is built up which eventually allows of direct distribution at any neutral point. If this modification is used it will be seen that Mr. Hrennikoff's alternative method is similar to it in general idea.

The writer, familiar with both Mr. Hrennikoff's and Professor Cross' analysis of this problem, is inclined to favor the former if for no other reason than that it gives springing thrusts and moments directly without the arithmetic of Lines 24 to 33 in Fig. 18. On the other hand, with Mr. Hrennikoff's method there are the equations to be solved, although with his alternative method the number of these equations is greatly reduced. Both methods of course are powerful tools, each well adapted to the task, and the writer earnestly commends a study of both of them to those concerned with this type of analysis.

Fig. 18.

A. W. FISCHER,[21] ESQ. (by letter).—The author is to be commended for his efforts to simplify the solution of one of the widely discussed problems arising in structural engineering. His method is short and simple when the spans are all the same and symmetrical and the arch has been analyzed for fixed-end moments and thrusts; but when the fixed-end moments and thrusts are not given and the axis does not follow the axis as given in the papers[3] by Charles S. Whitney, M. Am. Soc. C. E., the method is still quite long especially for the analysis of three spans or more. In the latter case it seems that a simple algebraic solution developed by Mr. H. Yu[22] is at least as rapid, and the results will agree very closely since both methods are based on the deflection of curved beams.

When applied to the two-span arch, Example I (which is one of the cases treated by Mr. Whitney[3]), the results obtained by the author's method practically agree with those of Mr. Whitney. In order to demonstrate the simplicity and brevity of the author's method when the fixed-end moments and thrusts are given, and to show how the results compare with other methods, it seems desirable to present the calculations in detail for a unit vertical load at a definite point. (All computations in this discussion were made with a 20-in. slide-rule.)

TABLE 4.—END DISTRIBUTION FACTORS OF RIBS AND PIER FOR NUMERICAL EXAMPLE I (DIVIDED BY E)

ROTATION FACTORS			DISPLACEMENT FACTORS		
Equation No.	Factor	Value	Equation No.	Factor	Value
(7)	h_{Fa}	0.5736 in.^{2}	(12)	$h_{F\Delta}$	0.004034 in.
(7)	h_{Na}	—0.5736 in.^{2}	(11)	$h_{N\Delta}$	—0.004034 in.
(5)	m_{Na}	—10.11 in^2–ft	(13)	$m_{N\Delta}$	—0.04780 in-ft.
(6)	m_{Fa}	4.815 in^2–ft	(13)	$m_{F\Delta}$	0.04780 in-ft.
(16)	h_{Ta}	2.151 in^2	(19)	$h_{T\Delta}$	—0.007493 in.
(17)	m_{Ta}	—76.93 in^2–ft	(20)	$m_{T\Delta}$	0.1794 in-ft.

The values in Table 4 have been calculated by using those given in Mr. Whitney's papers[3] and substituting in Equations (5) to (20), inclusive, of this paper. Table 5 is arranged in a manner similar to Table 3 of the paper and gives the values for a unit vertical load at the 0.9th point[23] of the two-span arch on an elastic pier as given in Example I in Mr. Whitney's papers.[3] Moments are expressed in foot-pounds and thrusts in pounds. (For other values of the two-span forces for unit vertical loads at Points 0.8 to 0.1, as calculated by the author's method, see Table 6.)

The structure is analyzed for a unit vertical load at the tenth points,[23] and it is assumed that the base of the pier and the abutments are considered absolutely fixed. In Tables 4 and 5 the sign conventions adopted by the author were used since they are very simple to follow; but in Table 6 the Whitney sign convention was used. On comparing values in Table 6 with what Mr. Whitney[24] gives, it is seen that the two methods agree rather well, and for the two-span arch on an elastic pier the Hrennikoff method is a quick solution for the moments and thrusts.

[24] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), Table 11, Example I, pp. 1118–1119.

A. A. EREMIN,[25] ASSOC. M. AM. SOC. C. E. (by letter).—A simplified method of computing stresses in a system of multiple-arch spans on elastic piers has been developed in this paper. The table of moments and thrusts in Fig. 11 is a useful guide in the practical application of the method.

In using the alternative method developed by the author in Fig. 11, time may be saved by releasing points starting from the end span of a system. This is true especially in reference to a series of variable lengths of arch spans. The advantage is twofold: First, the error in computing distribution factors for moments and thrusts may be traced easily because the effect of one additional span on distribution factors is more evident than in the case of a series of spans in which the structure is divided into two or more series of spans as suggested by the author; and, second, the step of balancing distribution factors in far spans may be omitted because they are negligible.

Mr. Hrennikoff assumed that joints in a system of multiple-arch spans do not move vertically. If the support is compressible, forces at the joint are balanced after it has rotated through an angle, α, moved horizontally for a distance, Δ, and vertically for a distance, δ. The angle of rotation, and the horizontal and vertical displacements of the joint may be determined from the equations of equilibrium of the joint: $\Sigma H_B = 0$; $\Sigma V_B = 0$; $\Sigma M_B = 0$. Thus,

$$h_\alpha \alpha + h_\Delta \Delta + h_\delta \delta + h_B \text{ (fixed)} = 0 \ldots\ldots\ldots\ldots\ldots (36)$$

$$v_\alpha \alpha + v_\Delta \Delta + v_\delta \delta + v_B \text{ (fixed)} = 0 \ldots\ldots\ldots\ldots\ldots (37)$$

and,

$$m_\alpha \alpha + m_\Delta \Delta + m_\delta \delta + m_B \text{ (fixed)} = 0 \ldots\ldots\ldots\ldots\ldots (38)$$

in which, h_δ, m_δ = the horizontal force and moment factors, respectively, corresponding to a vertical displacement of a joint; v_α = vertical force factor with reference to an angle of rotation; v_Δ = vertical force factor with reference to a horizontal displacement; v_δ = vertical force factor with reference to a vertical displacement; and v_B = the sum of the fixed-end vertical forces at a joint from the given loading.

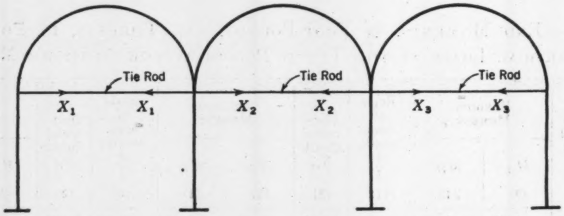

FIG. 19.—MULTIPLE-SPAN ARCH ON ELASTIC PIERS WITH TIE-RODS AT JOINTS.

Mr. Hrennikoff's method may be extended so that stresses can be computed in a system of multiple-arch spans on elastic piers with flexible tie-rods in arches, such as that in Fig. 19. Equations for computing stresses in tie-rods may be written according to Maxwell's theorem:

---

[25] Assoc. Bridge Designing Engr., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

$$X_1\,(\Delta_{11} + \Delta_1) + X_2\,\Delta_{21} + X_3\Delta_{31} = \Delta_{01} \ldots\ldots\ldots\ldots (39)$$

$$X_1\,\Delta_{12} + X_2\,(\Delta_{22} + \Delta_2) + X_3\,\Delta_{32} = \Delta_{02} \ldots\ldots\ldots\ldots (40)$$

and,

$$X_1\,\Delta_{13} + X_2\,\Delta_{23} + X_3\,(\Delta_{33} + \Delta_3) = \Delta_{03} \ldots\ldots\ldots\ldots (41)$$

in which, X_1, X_2, X_3 = stresses in the tie-rods (subscripts indicate number of the span); Δ_{01}, Δ_{02}, Δ_{03} = changes in lengths of spans at the tie-rods of the system (Fig. 19 with tie-rods removed and loaded with the given loading); Δ_{11}, Δ_{12}, Δ_{13} = changes in span lengths at the tie-rods when the system of arch spans is sustaining a unit force, $X_1 = 1$, acting along the axis of the tie-rod in the first span; Δ_{21}, Δ_{22}, Δ_{23} = changes in span lengths at the tie-rods when the system of arch spans is sustaining a unit force, $X_2 = 1$, acting along the axis of the tie-rod in the second span; Δ_{31}, Δ_{32}, Δ_{33} = changes in span lengths at the tie-rods when the system of arch spans is sustaining a unit force, $X_3 = 1$, acting along the axis of the tie-rod in the third span; and Δ_1, Δ_2, Δ_3 = changes in the lengths of tie-rods corresponding to a unit load acting along the axis of the tie.

Then: $\Delta_1 = \dfrac{L_1}{A_1\,E_s}$; $\Delta_2 = \dfrac{L_2}{A_2\,E_s}$; and $\Delta_3 = \dfrac{L_3}{A_3\,E_s}$, in which L_1, L_2, and L_3 = lengths of tie-rods; A_1, A_2, and A_3 = sectional area of tie-rods; and, E_s = modulus of elasticity in steel.

Stresses in a system of multiple-arch spans on elastic piers with removed ties (Fig. 19), sustaining external loading, or unit forces acting along the axes of the ties, may be determined by Mr. Hrennikoff's method. The horizontal displacements at tie-rods (Fig. 19) may be determined either graphically, or analytically. By solving simultaneously, Equations (39) to (41), stresses in the tie-rods (Fig. 19), X_1, X_2, and X_3, are determined. Equations similar to Equations (39) to (41) may be written for a system with any number of spans.

Computation of the stresses in a multiple-span arch on elastic piers has been generally recognized as an involved problem, and in simplifying it the author deserves the highest credit.

Alexander Hrennikoff,[28] Esq. (by letter).—The favorable attitude of discussers toward the method presented in this paper, and their general agreement with the writer leave no necessity for an extensive closure.

To Professor Grinter and Mr. Newmark the writer extends his thanks for further elucidation of the principles underlying the method and of its relation to Professor Cross' method of moment distribution. Professor Grinter prefers solution of the multiple-arch system by Larson's method of successive approximations in which the joints are allowed to rotate and to translate in succession, with the adjacent joints kept fixed temporarily. However, a very slow convergence of the series which results from such a procedure presents an obstacle to the successful application of the method—a fact which is mentioned in the discussions by Professor Finlay and Mr. Newmark.

---

[28] Instr., Dept. of Civ. Eng., Univ. of British Columbia, Vancouver, B. C., Canada.

It is this objection that led Professor Cross to devise his neutral-point method of analyzing multiple arches, in which the movements of the pierhead are replaced by the movements of the neutral point of the joint. Although it also deals with successive approximations this method is free from the disadvantage of slow convergence, and presents a powerful tool in multiple-arch analysis. It is very original and ingenious, but not as simple as appears on the surface, and the brevity of its presentation by Professor Cross[19] requires a novice to do considerable thinking before grasping its essence thoroughly.

Undoubtedly, this feature has been a hindrance to assimilation of this valuable method by the profession, and the discussion by Professor Finlay, popularizing Professor Cross' analysis, is most timely and appropriate. He takes great pains to explain the neutral-point method and to improve the form of computations. The writer agrees with Professor Finlay that a proper form, such as that of Fig. 18, is very necessary for orderly calculations of the results, especially if the method is intended for use in a designing office.

The same statement applies, of course, to the writer's tabulation of the solution for the four-span arch in Fig. 11. It is rather peculiar to notice in this connection that Professor Grinter does not approve of the table (Fig. 11), and believes that it obscures the physical side of the picture. This is exactly the opposite of the writer's opinion, and the suggested form of the table with small diagrams of arches on the left-hand side has been especially devised for the purpose of clarifying the successive physical steps taken. This tabular form, therefore, is an integral and important part of the method. It is practically self-explanatory if the reader only keeps in mind the following few simple facts:

1.—The given multiple arch is solved after considering arches of fewer spans;

2.—Each line contains moments and thrusts at various terminals in the structure drawn on the diagram when the encircled joint undergoes a rotation, α, or a horizontal displacement, Δ, of the magnitude stated in the column headed "Conditions";

3.—The necessary movements are determined by the solution of two simultaneous equations stated on the right-hand side and representing the conditions of equilibrium of the joint;

4.—The "joint distribution factors" utilized as coefficients before α and Δ in these equations are themselves determined along the same lines in the earlier part of the analysis (see the first ten lines of Fig. 11.).

The foregoing facts, as well as the supporting theory, seem quite simple to the writer; but of course he realizes that the advantage of familiarity may easily blind him to the difficulties inherent in his method. The judgment of disinterested engineers should be more reliable from this point of view; but most of the discussions are disappointingly general in nature, avoiding, for the most part, direct specific comments.

Mr. Fischer is the only discusser who made a detailed study of the writer's method as applied to a two-span arch. It is to be regretted that he did not extend his thorough investigation to the case of the four-span arch in which the advantages of the method become more pronounced. A two-span arch can be analyzed quite easily even by the otherwise cumbersome method developed by D. E. Larson, Jun. Am. Soc. C. E.

Mr. Lin's suggestion of using kip-inch units for moments instead of kip-feet units is not without merit. If inches and kips are used throughout for moments as well as for E, I, and A, the units of distribution factors cannot be in error. However, Mr. Lin is mistaken in claiming that such a choice of units provides a check on the solution. The equality of numerical values of certain distribution factors, discovered by him, follows from the identity of general expressions from which these numerical values are determined, and, consequently, does not check anything.

The problem of analyzing a multiple-arch system on elastic piers with flexible tie-rods in the arches, suggested by Mr. Eremin, suits the writer's method admirably. The tie-rods should be treated as separate members. Columns should be added in the computation table at each joint for each tie-rod. The single-span, displacement, thrust factor for a rod can be expressed by the formula:

$$h = \pm \frac{AE}{l} \qquad \text{(42)}$$

the sign being plus for the far end and minus for the near end. The three other distribution factors for the rod are each equal to zero. The factors for the rods, of course, are included with the others in the calculation of the joint distribution factors. Introduction of tie-rods, therefore, does not increase the complexity of the problem, and causes only a slight increase in the numerical work. The solution outlined by Mr. Eremin, consisting in removing the restraints caused by tie-rods, and in equating the deformations of the arches to the changes in length of the tie-rods, is very long, and has the disadvantages of other algebraic solutions based on the so-called "first principles."

To summarize the preceding discussion, the following methods have been proposed to date for the solution of open-rib multiple arches on elastic piers: (1) The algebraic method involving a number of simultaneous equations for the determination of the movements at the pier-heads; (2) the Larson method; (3) the neutral-point method by Professor Cross; and (4) the writer's method.

Method (1) is generally a long process. Method (2) is quite satisfactory for two-span arches; but is unwieldly for a greater number of spans, except when the piers are very rigid. With more than two spans the choice should be between Methods (3) and (4), the data so far available being insufficient to enable one to make a final selection.

RATIONAL DESIGN OF STEEL COLUMNS

By D. H. Young,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. William R. Osgood, Alfred S. Niles, J. F. Baker, K. L. De Blois, Marvin A. Gray, R. G. Sturm and Marshall Holt, F. E. Turneaure, N. J. Durant, E. C. Hartmann, Edward Godfrey, L. T. Wyly, and D. H. Young.

Synopsis

A basis for the design of steel columns is offered in this paper. The effect of general imperfections is represented by an assumed form of initial curvature of the axis of the column, or by an eccentricity in the application of the load; the loading first producing yielding in the most stressed fibers, due to the assumed curvature or eccentricity, is then used as the criterion for the selection of the working load.

The proposed method is applied to pin-ended columns under several conditions of loading, design formulas being developed for each case. In addition, an approximate solution is made for the case of columns in rigid frame construction.

The question of shear in built-up steel columns is treated on the same basis and for the same conditions of loading, formulas being developed for the design of lacing or batten-bars in such columns.

The paper represents, in somewhat condensed form, work done by the writer in preparing his thesis[2] entitled "Rational Design of Steel Columns."

Introduction

Since the time of Euler, the question of the resistance and stability of compression members has been controversial. The inherent difficulty with the column is that slight imperfections have a pronounced effect upon its

[2] Submitted to the Univ. of Michigan in 1934, in partial fulfillment of the requirements for the degree of Doctor of Science in Civil Engineering.

behavior under load. The chief factors that affect the behavior of the column may be listed, as follows: (1) Imperfect elasticity of the material; (2) initial crookedness of the axis; (3) accidental eccentricity in the application of load; and (4) uncertainty of conditions at the ends of the column. Theories that do not take into account the extent of the effect of such imperfections are of little practical value to the designer.

As a result of such influences as Factors (1) to (4), it is present-day practice to design columns by empirical formulas. Because such formulas are backed by considerable experience, and because they generally use a liberal factor of safety, they have proved satisfactory, in most cases. The designer, however, has at his disposal such a variety of formulas that widely different results can be obtained for the same column. Curves are available[3] showing the relation between the allowable average compressive stress and the slenderness ratio, as prescribed for steel columns by various building codes and specifications in the United States. Taken altogether, such curves represent a band across the range of slenderness ratios fully 10 000 lb per sq in. wide. Of course, in all justification, it must be admitted that they represent a wide range of conditions, and each of them carries with it a number of restrictions upon its use, so that, finally, there is not the utter state of confusion that might be apparent at first glance. However, such a collection of curves is far from representing any unified agreement regarding the strength of steel compression members.

Granting the sufficiency of such empirical formulas for ordinary cases, it seems desirable to have a more general theoretical basis for design, which will take into account as far as possible all necessary factors. A rational formula has the advantage of being consistent over a much wider range of conditions than the empirical formula. Furthermore, it may show how Factors (1) to (4) affect the strength of the column, and thus the designer can make some saving in material by a careful control of workmanship or material; again, experiments conducted in the light of some kind of a rational theory, even if it is far from perfect, can yield far more valuable results than experiments conducted more or less blindly.

NOTATION

The symbols used throughout the paper are given in the Appendix. An effort has been made to conform as nearly as practicable with the "Symbols for Mechanics, Structural Engineering, and Testing Materials" advanced by the American Standards Association.[4]

PART I.—COLUMNS OF SOLID CROSS-SECTION

1.—BASIS FOR DESIGN

Nature of the Material.—A typical stress-strain diagram for ordinary mild steel is shown in Fig. 1. The curve has three significant points: (1) The proportional limit; (2) the yield point; and (3) the ultimate strength. One of these three points is usually taken as a basis when considering allowable working stresses.

---

[3] For example, see "Steel Construction," Manual of the Am. Inst. of Steel Construction, First Edition, 1933, p. 176.

[4] A S A—Z10*a*—1932.

At one time working stresses used in design were based on the ultimate strength of the material. This was illogical because, at the same time, stresses were computed on the assumption that Hooke's law applied. On such a basis the designer had no such factor of safety against failure as he assumed.

At present, the yield point of the steel is quite generally recognized as the limit of usefulness. The deformation which takes place during yielding is generally from ten to fifteen times the elastic deformation at the proportional limit. Such yielding, while not properly representing complete failure, results in structural damage which cannot be allowed in ordinary structures.

To analyze a structure, the ordinary equations of elasticity based upon Hooke's law can be used, strictly speaking, only for stresses within the proportional limit. For stresses beyond this the true shape of the stress-strain diagram (Fig. 1) must be taken into account, and the problem frequently becomes very complex. In general, the effect of a slight deviation from a straight line between the proportional limit and the yield point will be small and can be safely neglected.

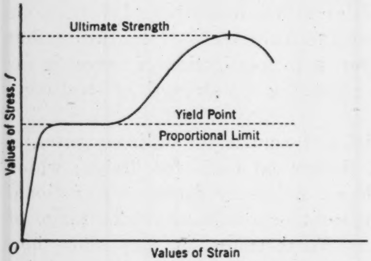

FIG. 1.—TYPICAL STRESS-STRAIN DIAGRAM FOR MILD STEEL.

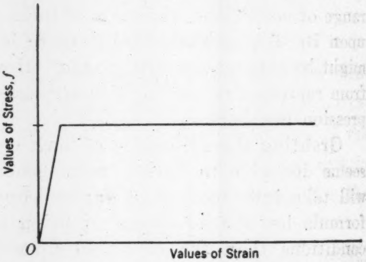

FIG. 2.—IDEAL STRESS-STRAIN DIAGRAM.

Assuming that the material is perfectly elastic up to the yield point, and interpreting yielding as failure, amounts to assuming a stress-strain diagram such as that shown in Fig. 2. It is, therefore, expedient and justifiable, in every way, to work with such an ideal stress-strain curve, and this is the usual practice. Furthermore, it is present-day practice to select the allowable loads for beams, subjected to bending, on the basis of the load that first produces a stress in the extreme fibers equal to the yield point, notwithstanding the fact that the beam will not collapse completely until all the inner fibers have begun to yield or until the extreme fibers have actually ruptured. It is well known that a beam of I-section is much nearer complete collapse when the extreme fibers first begin to yield than a beam of circular or rectangular cross-section. It is not usual practice in structural design, however, to take any account of this reserve strength against complete collapse in the case of the circular or rectangular cross-section; but rather to take the beginning of yielding in the extreme fibers as the criterion for design. In other words, this kind of structural damage is interpreted as failure.

Thus, all difficulty with Factor (1) (imperfect elasticity of the material) is eliminated. It will be logical to approach the problem of column design in the same way. To establish the logic of such a treatment, it will be convenient to consider qualitatively the general behavior of columns under load before going into more detail.

A Perfectly Straight, Axially Loaded, Pin-Ended Steel Column.—If the perfectly straight, pin-ended, steel column shown solid in Fig. 3(*a*), is slender, so that the Euler load may be reached before the fiber stresses become equal to the proportional limit, the load-deflection diagram is similar to Curve *OABC* in Fig. 3(*b*). At first, as the load increases, there is no lateral deflection. At the Euler load, P_e, the column becomes elastically unstable and may have any small deflection. A very slight increase in load above the Euler value produces a large lateral deflection. (For an increase of load 1% above the Euler value the lateral deflection at the center becomes in the order of 9% of the length of the bar.) As the load increases there finally comes a point beyond which the load necessary to maintain further deflection falls off rapidly. Before this occurs, however, the stresses in the extreme fibers will have passed the yield point. Point *B*, corresponding to the maximum load which the column can carry, represents the buckling load and is slightly greater than the Euler load.

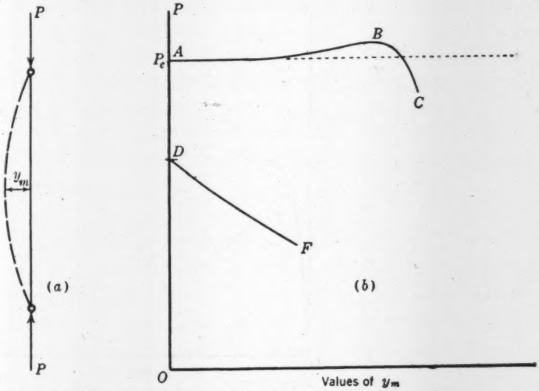

FIG. 3.—BEHAVIOR OF AN INITIALLY STRAIGHT, AXIALLY LOADED COLUMN.

If the column is short enough so that the average compressive stress becomes equal to the yield-point stress before the Euler load is reached, the load-deflection diagram will be similar to Curve *ODF* in Fig. 3(*b*). The column remains straight for loads up to the maximum load at Point *D*, which corresponds approximately to the yield point, and then buckles suddenly, the load necessary to maintain any deflection falling off rapidly as the deflection is increased. The theory of such inelastic buckling was first developed by F. Engesser[5] in 1891.

Initially Curved or Eccentrically Loaded, Pin-Ended Steel Columns.—When a slender column is initially curved, or straight and eccentrically loaded, as represented in Fig. 4(*a*) and Fig. 4(*b*), the load deflection diagram will be similar to Curve *OABC* in Fig. 4(*c*). For any value of the load there is a definite lateral deflection. This deflection increases very slowly until the load approaches the Euler value, after which it begins to increase rapidly to some point, beyond which the load necessary to maintain further deflection falls off. Point *B*, corresponding to the maximum load which the column can carry, represents the buckling load. Before this load is reached the maximum fiber stresses will have passed the yield point.

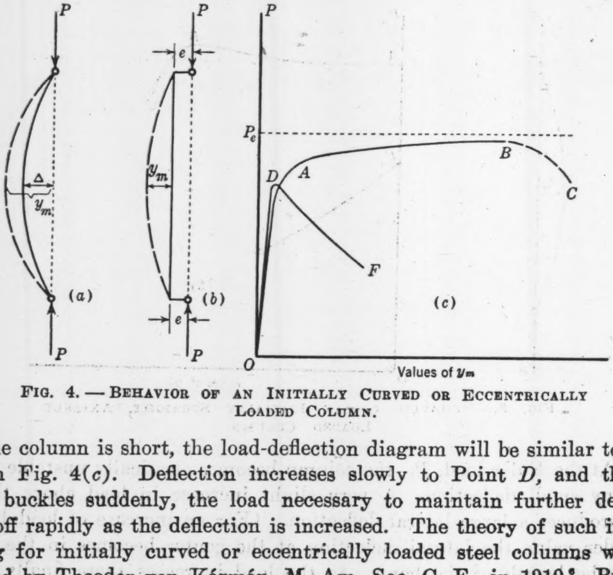

FIG. 4. — BEHAVIOR OF AN INITIALLY CURVED OR ECCENTRICALLY LOADED COLUMN.

If the column is short, the load-deflection diagram will be similar to Curve *ODF* in Fig. 4(*c*). Deflection increases slowly to Point *D*, and then the column buckles suddenly, the load necessary to maintain further deflection falling off rapidly as the deflection is increased. The theory of such inelastic buckling for initially curved or eccentrically loaded steel columns was first developed by Theodor von Kármán, M. Am. Soc. C. E., in 1910.[6] Professor von Kármán also obtained such curves as those in Fig. 4(*c*), experimentally, and succeeded in getting remarkable agreement with the theory.

The determination of the curves, as shown in Fig. 4(*c*), must take account of the slenderness ratio of the column, the shape of the cross-section, the true characteristics of the stress-strain diagram (Fig. 1), and the manner of loading. The labor involved in making these calculations is great, and also a definite stress-strain diagram must be assumed. Since the variation in the yield point of steel for various specimens is probably as much as ± 10%, this limitation would not seem to warrant such refinement in calculating buckling loads, for purposes of design, as has been outlined.

[6] "Untersuchungen über Knickfestigkeit," *Forschungsarbeiten*, Nr. 81, 1910; see, also, "Strength of Steel Columns," by H. M. Westergaard, M. Am. Soc. C. E., and William R. Osgood, Assoc. M. Am. Soc. C. E., *Transactions*, A. S. M. E., Vol. 49–50 (Paper APM 50–9), 1927–28.

Furthermore, due to the sudden nature of inelastic buckling, it is obvious that the fiber stresses have gone past the yield point before complete buckling occurs. It is doubtful, therefore, whether the buckling load should be used as a criterion for the design of columns any more than the loads that produce complete collapse of a beam should be used as the criterion for the selection of design loads. It would seem more consistent to design columns on a basis of the loading that first produces extreme fiber stresses equal to the yield point, as is done in the case of beams.

Finally, the introduction of initial curvature or eccentricity of load makes the column problem always one of combined bending and direct stress. Consider, for example, the eccentrically loaded column shown in Fig. 4(*b*). As the eccentricity, *e*, varies from zero to infinity, the complete range from pure compression to pure bending is covered. Since most compression members in structures are subjected to bending as well as to compression, it seems desirable to have one basis of design consistent throughout this range. The loading first producing a maximum fiber stress equal to the yield point will furnish such a basis.

Basis for Design.—From the foregoing discussion the following basis for the design of pin-ended steel columns is proposed: Take a column with some definite initial curvature of the axis or eccentricity of load to represent the effect of all imperfections, and then use the loading that first produces yielding in the extreme fibers as a basis for the selection of the working load, using any desired factor of safety; that is, if P_y denotes the load that first produces yielding due to assumed initial curvature or eccentricity, and n, the desired factor of safety, then the allowable working load, P_w, is to be obtained by the formula:

$$P_w = \frac{P_y}{n} \qquad \text{(1)}$$

2.—IMPERFECTIONS REPRESENTED BY INITIAL CURVATURE

The purpose of studying the behavior of an initially curved bar under compressive loads will be to learn the effect of possible accidental initial curvature on the strength of the column. Such accidental initial curvature of the bar may be of almost any shape. For a given initial deflection the most serious condition for the bar (as far as bending stresses are concerned) will be a curve, such that all points on the axis of the bar are displaced on the same side of a straight line through the ends. Various types of curvature satisfying this condition are the arc of a circle, a parabola, a half sine curve, etc. Since actual accidental initial curvature is as likely to be approximated by one of these curves as another, it seems logical to assume the form that can be most simply handled mathematically. For this reason the half wave of a sine curve will be chosen.

Consider a bar initially curved as shown in Fig. 5. The maximum deviation from a straight line at the center of the bar is Δ, and the initial deflection at any other point distant, x, from the left end, will be given by the expression:

$$y_0 = \Delta \sin \frac{\pi x}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

When such an initially curved bar is acted upon by compressive end loads, P, as shown, the bar assumes a definite shape for each value of the load.

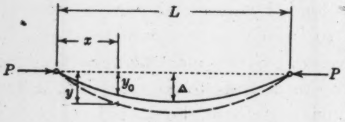

FIG. 5.—INITIALLY CURVED PIN-ENDED COLUMN.

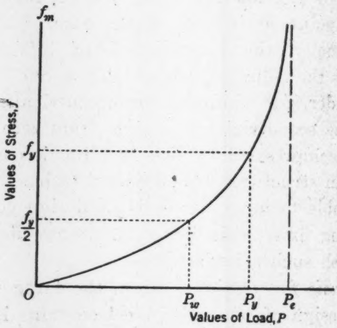

FIG. 6.—NON-LINEAR RELATIONSHIP BETWEEN AXIAL LOAD AND MAXIMUM FIBER STRESS.

Choosing the original of co-ordinates at the left end of the bar, the general relation between curvature and bending moment at any section will be,

$$EI\left(\frac{d^2y}{dx^2} - \frac{d^2y_0}{dx^2}\right) = -Py \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Equation (3), of course, holds only for a fairly flat deflection curve; also it is based on the assumption that Hooke's law applies. The possibility of buckling perpendicular to the plane of bending is not considered. Substituting the value of $\frac{d^2y_0}{dx^2}$ from Equation (2) and letting the quantity, $\frac{P}{EI} = q^2$, gives:

$$\frac{d^2y}{dx^2} + q^2 y = -\frac{\pi^2}{L^2}\,\Delta \sin \frac{\pi x}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Equation (4) represents the differential equation of the elastic line of the bar and its solution is,

$$y = C_1 \sin q\,x + C_2 \cos q\,x + \frac{\Delta\,\pi^2}{\pi^2 - q^2 L^2} \sin \frac{\pi x}{L} \quad \ldots\ldots (5)$$

in which, C_1 and C_2 are constants to be evaluated from the end conditions of the bar. These constants will be: $C_2 = 0$; and $C_1 \sin q\,L = 0$. From the latter of these two conditions either $C_1 = 0$, or $\sin q\,L = 0$. If $\sin q\,L = 0$

then either $q\,L = 0$, or $q\,L = i\,\pi$, in which, i is any integer. From these two conditions either $P = 0$, or $P = \dfrac{i^2\,\pi^2\,E\,I}{L^2}$. The condition, $P = 0$, obviously holds no significance. For the second condition, P is seen to represent the Euler load for the bar, in which case the deflection becomes infinite. It follows, then, that for finite deflections, $C_1 = 0$ must be taken. Equation (5) then reduces to,

$$y = \frac{\Delta\,\pi^2}{\pi^2 - q^2\,L^2}\,\sin\,\frac{\pi\,x}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (6)$$

Equation (6) defines the axis of the bar for any value of the load between $P = 0$ and $P = P_e$. The deflection will be a maximum at the center of the bar. Making $x = \dfrac{L}{2}$, in Equation (6), gives,

$$y_m = \frac{\Delta\,\pi^2}{\pi^2 - q^2\,L^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (7)$$

Substituting $q^2 = \dfrac{P}{E\,I}$, and $\dfrac{\pi^2\,EI}{L^2} = P_e$, Equation (7) may be written:

$$y_m = \Delta\left(\frac{1}{1 - \dfrac{P}{P_e}}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (8)$$

The maximum bending moment, at the center of the bar, will be $P \times y_m$, or,

$$M_m = \Delta\left(\frac{P}{1 - \dfrac{P}{P_e}}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (9)$$

The maximum fiber stress, in the outside fiber, on the concave side of the bar will be,

$$f_m = \frac{P}{A} + \frac{M_m}{S} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (10)$$

in which, S is the section modulus of the cross-section. Substituting the value of M_m into Equation (10) gives,

$$f_m = s\left[1 + \frac{\Delta}{k}\left(\frac{1}{1 - \dfrac{s}{s_e}}\right)\right] \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (11)$$

in which, $k = \dfrac{S}{A}$ is the core radius of the cross-section; $s = \dfrac{P}{A}$ is the load per unit area or average compressive stress; and $s_e = \dfrac{P_e}{A} = \dfrac{\pi^2\,E}{\left(\dfrac{l}{r}\right)^2}$. The use of the core radius, k, makes possible a simple interpretation of Equation (11). If a short block is compressed by a load, P, applied with an eccentricity, $e = \Delta$, the maximum compressive stress from Equation (10) becomes, $f_m = \frac{P}{A}\left(1 + \frac{\Delta}{k}\right)$. The term, $\frac{\Delta}{k}$, then represents the ratio of the bending stress to the direct compressive stress. The term, $\left(\frac{1}{1 - \frac{s}{s_e}}\right)$, in Equation (11), may now be considered as a magnification factor which shows the effect, on the bending stress, of taking into account the deflections of the bar. The ratio, $\frac{\Delta}{k}$, will be called the eccentricity ratio. Equation (11) gives the maximum fiber stress for any given value of the load, P, and any amount of initial curvature as represented by Δ.

Making $f_m = f_y$ and, at the same time, denoting the corresponding average compressive stress by s_y, Equation (11) may be written:

$$s_y = \frac{f_y}{1 + \frac{\Delta}{k}\left(\frac{1}{1 - \frac{s_y}{s_e}}\right)} \quad \text{.....................(12)}$$

which gives the load per unit area first producing a maximum fiber stress equal to the yield point.

If values of f_m computed from Equation (11) are plotted against the load, P, a curve such as that shown in Fig. 6 is obtained. It is seen from this curve that no proportionality exists between load and maximum fiber stress. This means that merely to assume a safe working stress, say, one-half the yield point (Fig. 6), and to use this in Equation (11) to compute the safe working load, is not permissible. Any desired factor of safety, however, may be incorporated directly into Equation (11) as follows: Assume that P_w is the allowable load and n is a factor of safety, such that the maximum stress becomes equal to the yield point when the load becomes equal to $n\ P_w$. If, in Equation (11), the load per unit area, s, is replaced by $n\ s_w$, and, at the same time, f_y is substituted for f_m, Equation (11) becomes:

$$s_w = \frac{f_y}{n + \frac{n\,\Delta}{k}\left(\frac{1}{1 - \frac{n\,s_w}{s_e}}\right)} \quad \text{................(13)}$$

The value of s_w computed from Equation (13) will always be such that n times this value will produce a maximum fiber stress equal to the yield point, and, hence, the desired factor of safety is realized. The appearance of n in the magnification factor then takes care of the lack of proportionality between load and fiber stress. This manner of incorporating a factor of safety, n, in formulas similar to Equation (13), was proposed by K. S. Zavriev,[7] who also calculated tables of allowable average stresses for various kinds of combined bending and compression of bars.

Curves may also be plotted from Equation (12) for any given value of f_y and various values of the eccentricity ratio, $\frac{\Delta}{k}$. These curves will show the average compressive stress, s_y, as a function of the slenderness-ratio, $\frac{L}{r}$, at which yielding will first begin. Any desired factor of safety, n, may also be obtained by simply dividing the value of s_y, read from the curve, by the desired factor of safety. Such a set of curves for a steel having a yield point of 36 000 lb per sq in., and values of $\frac{\Delta}{k}$ ranging from 0 to 1.0, is shown in Fig. 7.

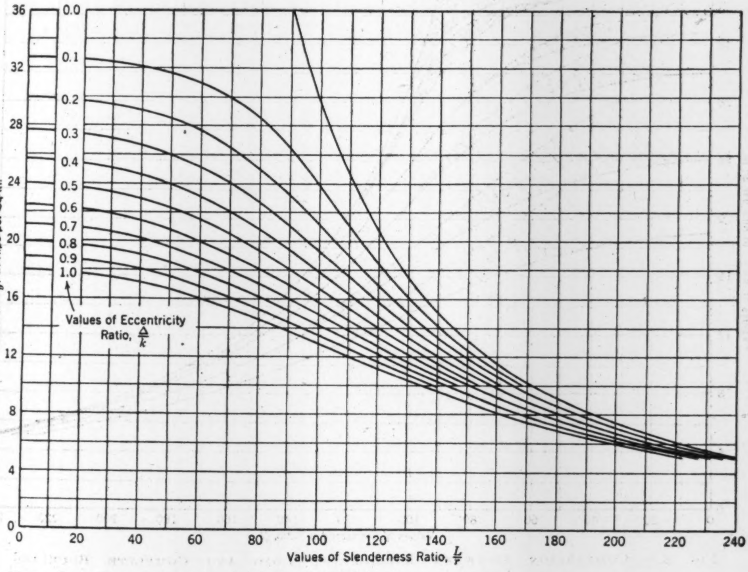

FIG. 7.—YIELD-POINT LOAD FOR VARIOUS ECCENTRICITY RATIOS; INITIALLY CURVED COLUMN.

It will be interesting to compare the values of the average compressive stress that first produce yielding with those[6] that cause buckling (complete failure) of the column, as discussed in Section 1. In Fig. 8, this comparison is made for the same steel, having a yield point of 36 000 lb per sq in., a proportional limit of 30 000 lb per sq in., and values of the eccentricity ratio ranging from 0.0 to 0.9. The curves for buckling apply only for columns of rectangular cross-section. For columns of I-section, the difference between corresponding curves will be less. The solid line curves show the value of average compressive stress at which yielding first begins, whereas the broken lines represent complete buckling. It will be seen from a study of these curves that for large values of $\frac{\Delta}{k}$ (more bending in proportion to direct stress), the buckling load is considerably greater for medium long columns than the yield-point load. As $\frac{\Delta}{k}$ decreases, the difference between corresponding curves becomes less. For values of $\frac{\Delta}{k}$ less than about 0.1, Equation (12) gives values of the load greater than the buckling load. This discrepancy on the side of danger, for nearly perfect columns, is of no consequence, since in the practical design of columns allowance will have to be made for values of $\frac{\Delta}{k}$ greater than 0.1. In general, it may be stated that the difference between the yield-point load and the load for complete collapse is always less for columns than for beams.

---

[7] *Bulletin*, Soc. of the Engrs. of Technology, St. Petersburg, 1913.

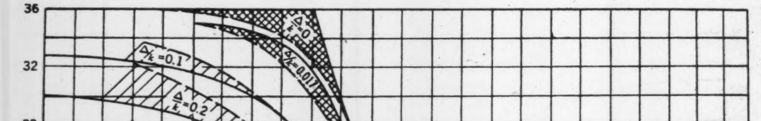

FIG. 8. — COMPARISON BETWEEN YIELD-POINT LOAD AND COMPLETE BUCKLING LOAD; INITIALLY CURVED COLUMN.

Design of a column by the trial and error method may now be made readily by the use of the curves in Fig. 7. The only factor difficult to decide upon is the proper value of the eccentricity ratio, $\frac{\Delta}{k}$, to be used. It has been shown[8] that the effect of any small accidental eccentricity of load on the column can be represented by some definite curvature of the axis. All imperfections of the column are then representable by some "equivalent curvature." Deviation from a straight line, of the axis of the column, due to accidental crookedness undoubtedly increases with the length of the column. It seems logical, therefore, that the eccentricity ratio selected to take care of such imperfections should be some function of the length. The proper function can be determined only on the basis of carefully conducted tests. Professor H. Kayser,[9] by working backward from test results to find the amount of initial curvature which must have been present, found values of Δ ranging from $\frac{L}{400}$ to $\frac{L}{1\,000}$. He recommended the use of $\Delta = \frac{L}{400}$ as a safe allowance for the effect of imperfections. E. H. Salmon[8] has made a study of this question and, on the basis of tests made by a number of experimenters, recommends the use of a value of $\Delta = \frac{L}{750}$.

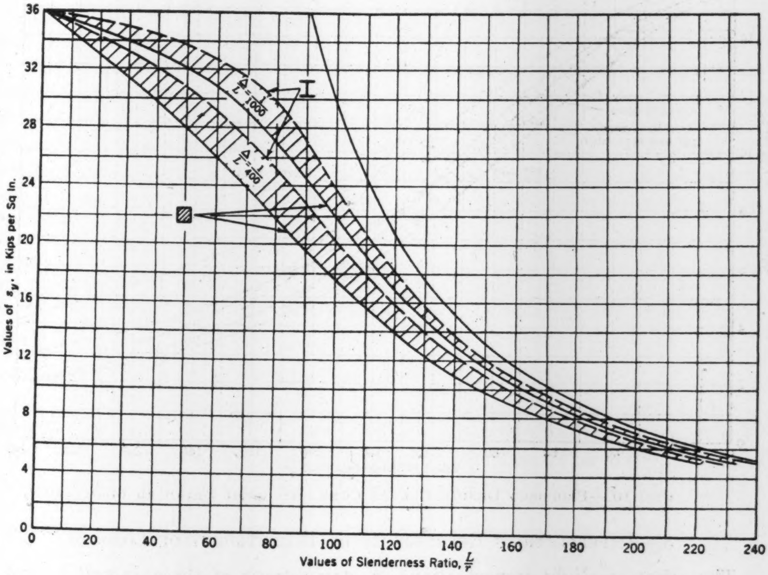

FIG. 9.—PROPOSED DESIGN CURVES FOR PIN-ENDED COLUMNS.

From the curves in Fig. 7 it is possible to derive a single curve for any given relation between Δ and L. For a steel having $f_y = 36\,000$ lb per sq in., and $\Delta = \dfrac{L}{400}$ and $\Delta = \dfrac{L}{1\ 000}$, four such curves are shown in Fig. 9, for columns of rectangular cross-sections and for columns having extreme I-sections; that is, having all the material concentrated at the radius of gyration from the axis. Granting that a column of I-section is not likely to have any more initial crookedness than one of rectangular cross-section of the same length, it is seen that the I-section is more efficient in this respect.

[8] "Columns," by E. H. Salmon, Oxford Technical Publication, p. 152.

[9] "Knickversuche mit doppelteiligen Rahmenstaben," *Die Bautechnik*, Vol. 12, Berlin, 1930.

For $\Delta = \dfrac{L}{400}$ the two curves in Fig. 9, plotted with a factor of safety, $n = 2.25$, are shown in Fig. 10 in comparison with standard American specifications for column design as approved by the Society,[8] the American Railway Engineering Association,[8] and the City of Boston, Mass.[8] (The value, 2.25, is selected to make the result comparable with the usual standard formulas based on a working stress of 16 000 lb per sq in.)

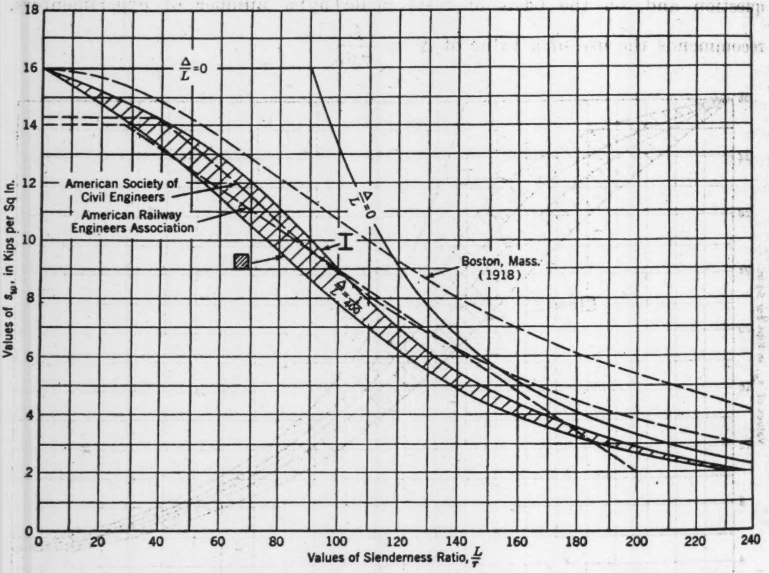

FIG. 10.—PROPOSED DESIGN CURVES COMPARED WITH STANDARD FORMULAS.

3.—IMPERFECTIONS REPRESENTED BY ECCENTRICITY OF LOAD

The effect of slight imperfections in straightness of the axis and central application of load, has been studied in Section 2 on the basis of some definite amount of "equivalent curvature." These imperfections can also be represented by some "equivalent eccentricity" of load on a straight column with a given amount of eccentricity, *e*. The most serious condition (for direct and bending stresses) will be obtained when the eccentricities are on the same side as shown in Fig. 4(*b*). For any value of the load, P, the bar assumes a definite shape and the maximum fiber stress, which occurs at the mid-cross-section, is given by the well-known secant formula which may be written in the form:

$$f_m = s\left[1 + \frac{e}{k}\sec\left(\frac{L}{2r}\sqrt{\frac{s}{E}}\right)\right] \ldots\ldots\ldots\ldots\ldots (14)$$

When the maximum fiber stress is taken equal to the yield point, Equation (14) may be written,

$$s_y = \frac{f_y}{1 + \frac{e}{k}\sec\left(\frac{L}{2r}\sqrt{\frac{s_y}{E}}\right)} \ldots\ldots\ldots\ldots\ldots (15)$$

In the same manner as before, any desired factor of safety, n, can be incorporated in Equation (14) giving:

$$s_w = \frac{f_y}{n + \frac{n\,e}{k}\sec\left(\frac{L}{2r}\sqrt{\frac{n\,s_w}{E}}\right)} \ldots\ldots\ldots\ldots\ldots (16)$$

Curves, almost identical with those plotted from Equation (12) (Fig. 7), may be plotted from Equation (15).

Due to the transcendental function which appears in Equation (15), it is not so readily solved as Equation (12). Approximations of Equation (15) have been suggested, which eliminate the secant function, but this simply reduces it to the same form as Equation (12), which is just another way of stating that the effects of eccentricity and initial curvature on the strength of a column are approximately the same. Since the imperfections which are to be represented by the eccentricity ratio, $\frac{e}{k}$, are of a highly indeterminate nature, there is no particular reason for representing them by "equivalent eccentricity" when they can be equally well represented by "equivalent curvature."

4.—GENERAL CASE OF ECCENTRIC LOADING

The General Eccentricity Formula.—The secant formula, discussed in Section 3, is in reality only a special case of eccentric loading in which the eccentricities are equal and on the same side of the axis (Fig. 4(*b*)). In general, a column may be loaded eccentrically, as represented in Fig. 11. In

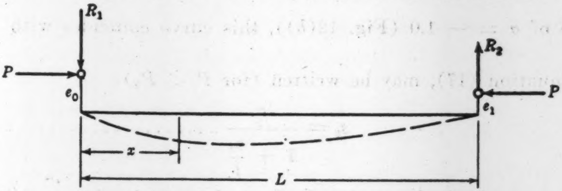

FIG. 11.—GENERAL CASE OF ECCENTRIC LOADING.

the diagram the eccentricity, e_0, at the left end is understood to be the larger of the two and is considered as positive, while e_1, the smaller eccentricity, is considered either positive or negative as it is on the same side as e_0, or on the opposite side.

An analysis of this case shows that as long as the load is less than a certain value, which will be denoted by P_q, the maximum bending moment, and consequently, the maximum fiber stress, occurs at the left end and is simply obtained from the equation (for $P < P_q$):

$$f_m = \frac{P}{A}\left(1 + \frac{e_0}{k}\right) \quad \text{.....................}(17)$$

The value of P_q is given by the equation:

$$s_q = \frac{P_q}{A} = \frac{(\cos^{-1} \alpha)^2 E}{\left(\dfrac{L}{r}\right)^2} \quad \text{.....................}(18)$$

in which, $\alpha = \dfrac{e_1}{e_0}$, and may vary from + 1 to − 1. Curves representing s_q as a function of $\dfrac{L}{r}$ for various values of α, can be drawn similar to those shown by broken lines in Fig. 12, which are for $\alpha = +\ 0.5$ and $\alpha = -\ 1.0$.

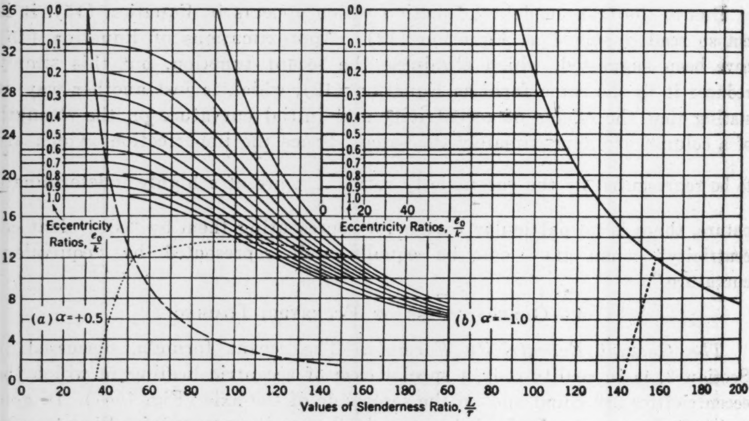

FIG. 12.—YIELD-POINT LOAD FOR VARIOUS ECCENTRICITY RATIOS: (a) ECCENTRICALLY LOADED COLUMN (a) $\alpha = +\ 0.5$; (b) $\alpha = -\ 1.0$.

In the case of $\alpha = -\ 1.0$ (Fig. 12(b)), this curve coincides with the Euler curve.

From Equation (17), may be written (for $P < P_q$):

$$s_y = \frac{f_y}{1 + \dfrac{e_0}{k}} \quad \text{.........................}(19)$$

which serves as a basis for design loads, as long as it gives a value for the average compressive stress less than the value given by Equation (18). Looking at this limiting case in another way, by making s_q in Equation (18) equal to s_y in Equation (19) and solving for the corresponding value of $\left[\frac{L}{r}\right]_a$ gives:

$$\left[\frac{L}{r}\right]_a = (\cos^{-1} \alpha) \sqrt{\frac{E}{f_y}\left(1 + \frac{e_0}{k}\right)} \qquad \ldots\ldots\ldots\ldots\ldots(20)$$

Thus, as long as the slenderness ratio of the column is less than the value determined by Equation (20), Equation (19) may be used as a basis for design. It is seen that, especially for negative values of α (bending in a reverse curve), the $\frac{L}{r}$ - range within which Equation (19) may be used, is very large.

This much of the analysis, for loading as represented in Fig. 11, was presented by C. N. Ross, in 1927, who applied it to the case of secondary stresses in truss members.[10]

Referring again to Fig. 11: When the load, *P*, reaches a value greater than P_q, the section of maximum bending moment, and, consequently, of maximum fiber stress, occurs at some intermediate point along the column. As a result of this fact the maximum stress is now a function of the deflection of the axis, and Equation (17) is no longer valid. An analysis of this case[11] leads to the equation (for $P > P_q$):

$$f_m = s\left[1 + \frac{e_0}{k}(\psi \csc \phi)\right] \qquad \ldots\ldots\ldots\ldots\ldots(21)$$

in which, $\phi = \frac{L}{r}\sqrt{\frac{s}{E}}$, and $\psi = \sqrt{\alpha^2 - 2\,\alpha \cos \phi + 1}$. As before, making $f_m = f_y$, and denoting the corresponding value of average compressive stress by s_y, gives (for $P > P_q$):

$$s_y = \frac{f_y}{1 + \frac{e_0}{k}(\psi \csc \phi)} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

which serves as a basis for design loads for all cases to which Equation (19) cannot apply. It will be seen that when $\alpha = +1$ (equal eccentricities on the same side), Equation (22) will reduce to Equation (15).

For various values of $\alpha = \frac{e_1}{e_0}$ curves may be plotted from Equations (19) and (22), which will show the average compressive stress, at which yielding first begins, as a function of the slenderness ratio of the column. For a steel having $f_y = 36\,000$ lb per sq in., and values of $\alpha = +0.5$ and -1.0, characteristic curves are shown in Fig. 12.

---

[10] "Equivalent Eccentricities Due to Secondary Stresses," C. N. Ross, *Transactions*, Inst. of Engrs. of Australia, Vol. VIII (1927), p. 8.

[11] See the writer's paper entitled, "Stresses in Eccentrically Loaded Steel Columns," *Publications*, International Assoc. for Bridge and Structural Eng., Vol. 1, Zurich, 1932, p. 507.

For practical purposes, a set of these curves for values of α progressing at intervals of 0.25, between the values of $+1.0$ and -1.0, can be drawn by the successive solution of Equations (19) and (22). Results for intermediate values of α can then be interpolated from these curves.

Allowance for the usual imperfections may be made in this case by the use of an "equivalent eccentricity" rather than "equivalent curvature." These accidental factors may occur in any form, and, therefore, the "equivalent eccentricity" should be chosen in the same direction at each end, since this is the most serious type. Using a value of, say, $e = \dfrac{L}{400}$, this "equivalent eccentricity" can be determined for any given column. Superposing this value of e at each end on the actual eccentricities, e_0 and e_1, will simply give modified values, e'_0 and e'_1, to be used in determining α. This modified value of α will then be used in selecting the yield-point load from the curves such as those in Fig. 12. The design load is obtained by dividing by the desired factor of safety.

Columns in Rigid Frame Construction.—One of the most important cases of column action to the structural engineer occurs in rigid frame construction, examples of which are shown in Fig. 13. Due to the elastic action of other members meeting at a joint, such a column acts intermediately between pin-ended and completely fixed-ended conditions. The determination of the actual condition requires the use of a theory of the stability of a system of compressed bars. Such a theory has been developed by Mises and Ratzersdorfer.[13] Their treatment, however, is based on the assumption that the material always behaves elastically and it does not determine the stresses that may arise, but rather considers only the problem of the elastic stability of such a system. Furthermore, its application to any system except the simplest becomes extremely laborious.

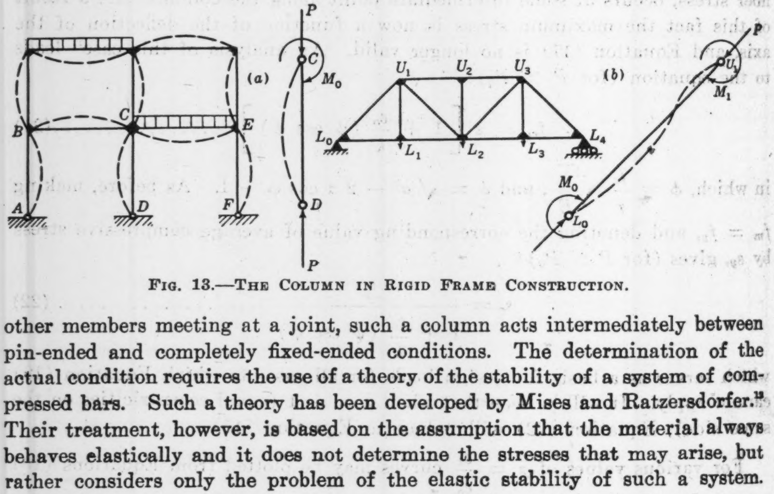

FIG. 13.—THE COLUMN IN RIGID FRAME CONSTRUCTION.

Since most compression members encountered in structural engineering are comparatively short, the maximum fiber stress is usually the governing factor in design rather than the elastic stability. In order to determine the stress that may occur in a column in a truss, consider the member, $L_0 U_1$, shown in Fig. 13(*b*). In addition to the axial compressive force, *P*, there will be secondary end moments, M_0 and M_1, arising due to the elastic action of the other members.

---

Mech.*, Vol. 3 (1923), pp. 406–422; also, "Die Knicksicherheit von Rahmentragwerken," von R. v. Mises und J. Ratzersdorfer, *Zeitschrift für angew. Math. u. Mech.*, Vol. 5 (1925), p. 218, and Vol. 6 (1926), p. 181.

An analysis of the maximum bending moment that may occur due to this loading, can be made in exactly the same manner as in the case of the type of loading represented in Fig. 11. The resulting equations for maximum bending moment will be:

$$M_m = M_0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(23)$$

as long as $s < s_q$, in which,

$$s_q = \frac{\left(\cos^{-1}\dfrac{M_1}{M_0}\right)^2 E}{\left(\dfrac{L}{r}\right)^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots(24)$$

and,

$$M_m = M_0 \;(\csc\phi)\sqrt{\left(\frac{M_1}{M_0}\right)^2 - 2\,\frac{M_1}{M_0}\cos\phi + 1} \;\ldots\ldots\ldots(25)$$

when $s > s_q$. In Equation (25), $\phi = \dfrac{L}{r}\sqrt{\dfrac{s}{E}}$, as before.

Using Manderla's exact method for computing secondary end moments, which is well known, the values of M_0 and M_1 can be expressed in terms of the axial force, *P*, for any given truss. In this way the loading that may first produce a maximum fiber stress equal to the yield point of the material can be established. The writer has made such calculations for several simple cases, but the labor involved is considerable even for two-member and three-member frames.

It is the usual practice, in computing secondary end moments, to neglect the effect of the axial load, *P*, on the lateral deflections produced in the bar. It is generally indicated that truss members are usually of such proportion that the effect of the axial force, *P*, in modifying the secondary end moments, is seldom more than 6% and usually much less.[13] In view of this fact, the excessive labor involved in using Manderla's exact method is scarcely considered justifiable.

Neglecting the effect of the axial force, *P*, on the deflections (in computing the values of secondary moments) amounts, however, to assuming that these moments increase in direct proportion to the axial force, *P*; that is, by making this approximation, the effect of the secondary end moments in Fig. 13(*b*) may be represented by the type of loading shown in Fig. 11, in which, e_0 and e_1 will be such that $P \times e_0 = M_0$ and $P \times e_1 = M_1$. Thus, columns in rigid frame construction may be designed on the basis of such curves as those presented in Fig. 12.

---

[13] "Statically Indeterminate Stresses," by John I. Parcel and George A. Maney, Members, Am. Soc. C. E., John Wiley & Sons, p. 321.

The procedure will be as follows: From the usual approximate method of calculating secondary end moments, the values of M_0 and M_1 for each member are determined. Dividing each by the axial force, P, the values of e_0 and e_1 are obtained. To make allowance for the effect of initial curvature and imperfections in general these values should be modified, as discussed previously, before computing $\alpha = \frac{e'_1}{e'_0}$ to be used in selecting the average compressive stress, s_y, from the curves (Fig. 12).

In the case of slender members this method of procedure will result in some error (on the side of safety, however). As was mentioned previously, Ross has proposed this same method of procedure for the design of compression members in trusses. He made a study[10] of a large number of existing structures of all types and found that in the great majority of cases the secondary end moments gave values of α such that the member came within the range of Equation (19) rather than Equation (22). Stated in another way, the slenderness ratio of the member was usually less than the value given by Equation (20). In all such cases, of course, the use of the curves (Fig. 12) represents no error at all. In practical cases, when the slenderness ratio is not less than the value determined by Equation (20), the error involved will usually be small and certainly on the side of safety.

PART II.—BUILT-UP STEEL COLUMNS

5.—Effect of Shear in Built-Up Columns

Stability.—Columns, as used in engineering structures, are frequently made of channels laced together by lattice-bars or batten-plates, as shown in Fig. 14. When such a column deflects laterally under load the cross-sections of the bar are no longer perpendicular to the end loads, and shearing forces are introduced. In the case of a column having a solid cross-section, the effect of such shearing forces is negligible, but in the case of built-up columns, the effect of the additional distortion due to shear must be taken into account.

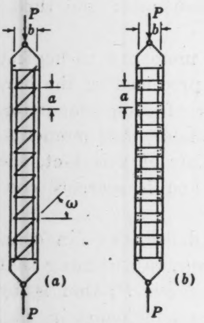

Fig. 14.—Built-Up Columns.

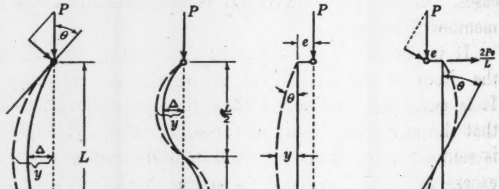

Fig. 15.—Possible Types of Initial Imperfections.

An analysis[14] of built-up columns shows that the critical load at which elastic instability occurs can be represented by the Euler equation in terms of a fictitious column having a length, L', thus:

$$P_c = \frac{\pi^2 E I}{(L')^2} \quad \dots\dots\dots\dots\dots\dots\dots\dots (26)$$

For the lattice-bar column (Fig. 14(*a*)), the fictitious length is given by the equation:

$$L' = L\sqrt{1 + \frac{\pi^2 E I}{L^2}\left(\frac{1}{\sin\omega\cos^2\omega\, E A_d} + \frac{b}{a E A_b}\right)} \quad \dots\dots (27)$$

in which, L = the true length of the column; ω = the angle between batten-bar and diagonal; A_d = cross-sectional area of two diagonal bars; A_b = cross-sectional area of two batten-bars; a = unsupported length of channels; and, b = distance between gravity axes of channels. For the batten-plate column (Fig. 14 (*b*)), the fictitious length is given by the equation:

$$L' = L\sqrt{1 + \frac{\pi^2 E I}{L^2}\left(\frac{a\,b}{12\,E I_b} + \frac{a^2}{24\,E I_c} + \frac{K_2\, a}{0.4\, b\, A_b G}\right)} \quad \dots\dots (28)$$

in which, a = distance center to center of batten-plates; b = distance between gravity axes of channels; I_c = moment of inertia of one channel about its gravity axis; I_b = moment of inertia of two batten-plates, with respect to gravity axis of bending; A_b = cross-sectional area of two batten-plates; K_2 = a coefficient = 1.2 for rectangular batten-plates; and G = shearing modulus for the battens.

The derivation, upon which these fictitious lengths are based, assumes an infinitely large number of panels. Practically, however, their use will give good results for a very limited number of panels. The specifications of the American Railway Engineering Association require that the slenderness ratio of the unsupported length of channel shall not be greater than $\frac{a}{r_c} = 40$. From a series of tests made on batten-plate columns, Kayser[15] concluded that Equation (26) gave results in good agreement with the tests for spacings of batten-plates considerably greater than the foregoing requirement.

A built-up steel column may be designed on a basis of the yield-point load obtained from the upper $\Delta = \frac{L}{400}$ - curve in Fig. 9 by using the fictitious length, L', as determined from Equation (27) or Equation (28), instead of the true length. Of course, the use of this curve, in which the initial curvature to represent the effect of imperfections has been taken as a function of the length, will amount to assuming the imperfections as a function of the fictitious rather than the true length. This will only result in giving a slight additional factor of safety which is probably not out of order for built-up columns.

---

[14] "Strength of Materials," S. Timoshenko, Pt. II (Van Nostrand), p. 592.

[15] "Knickversuche mit doppelteiligen Rahmenstaben," von H. Kayser, *Bautechnik*, Vol. 12, 1930.

Effect of Imperfections on Shearing Stresses.—It is present-day practice to design the lacing or batten-bars, empirically, to resist possible shearing forces. For example, the A.R.E.A. Specifications require that the lacing-bars shall be designed to resist shearing forces not less than 0.025 times the total compressive force on the column.

In discussing the design of lattice-bars and battens to resist possible shearing forces, it seems logical to proceed as before and assume, as a basis of computation, an imperfection in the form of initial curvature or eccentricity of load. When this has been selected, it will be possible to evaluate the maximum shearing force that arises for any value of the compressive load, P. This maximum shearing force will then be calculated for the value of the load, P_y, which first causes yielding in the extreme fibers. The shearing force thus calculated will be used as a basis for design. In this way the strength of the column in shear will be consistent with its strength in bending and thrust.

The imperfections should now be taken in the most serious form, as far as shearing forces are concerned. Possible types of such initial imperfections are represented in Fig. 15. Further consideration of some of these initial conditions to represent imperfection can be ruled out.

First, consider the imperfections as represented by the half wave of a sine curve shown as Case *a* in Fig. 15(*a*). For any value of the load, P, there will be a definite value of the angle, θ, at the end, and the maximum shearing force occurring here will be, $V = P \sin \theta$. In the second case, when the initial curvature is taken as a full sine curve (S-shaped), it will be logical to assume Δ as the same function of $\frac{L}{2}$ instead of L, and each half of the column will be identical with the previous case. However, since the column will buckle in one wave (regardless of its initial shape) at the Euler load for the length, L, this case can never give rise to as great shearing forces as Case *a*. Case *c*, likewise, will never be as serious as Case *a* because, at the load producing failure, the maximum bending moment at the center must be approximately the same for each case. In Case *a* this moment is $P \times y$, while, in Case *c*, it is $P\ (y + e)$; hence, y (and, consequently, θ, at the end) will always be less for the eccentrically loaded column. If θ is less, the shear, $P \sin \theta$, will be less.

Case *d* only, then, needs further consideration. When the eccentricities are chosen on opposite sides of the axis, definite horizontal reactions, $\frac{2Pe}{L}$, arise at the ends. Remembering that θ will be a small angle, it is seen from Case *d*, Fig. 15, that the shearing force will be a maximum at the center cross-section and equal to $\frac{2Pe}{L} + P \sin \theta$. It is possible that this condition may introduce greater shearing forces than will initial curvature. Cases *a* and *d,* in Fig. 15, will now be considered in more detail.

6.—SHEAR DUE TO IMPERFECTIONS REPRESENTED BY INITIAL CURVATURE

Considering Case *a,* Fig. 15, the equation of the elastic line is represented by Equation (6). Taking the first derivative of this equation with respect to x will give the slope at any cross-section as,

$$\frac{dy}{dx} = \frac{\Delta \pi^2}{\pi^2 - q^2 L^2} \frac{\pi}{L} \cos \frac{\pi x}{L} \qquad (29)$$

This will be a maximum at the end, where $x = 0$, and hence,

$$\tan \theta_m = \frac{\Delta \pi^2}{\pi^2 - q^2 L^2} \frac{\pi}{L} \qquad (30)$$

Substituting the values, $q^2 = \frac{P}{EI}$ and $P_e = \frac{\pi^2 EI}{L^2}$, Equation (30) may be written,

$$\tan \theta_m = \frac{\Delta \pi}{L} \frac{1}{1 - \frac{s}{s_e}} \qquad (31)$$

Since the maximum shearing force is $V = P \sin \theta_m = P \tan \theta_m$ (for small angles), Equation (31) may be written:

$$v = \frac{V}{A} = s \frac{\Delta \ \pi}{L} \frac{1}{1 - \frac{s}{s_e}} \qquad (32)$$

For any given slenderness ratio, $\frac{L}{r}$, the value of s, at which yielding first begins, is given by Equation (12). For a fixed value of $\frac{L}{r}$, this formula may be considered as representing the relation between the average compressive stress, s_y, for yielding, and the amount of initial curvature as represented by Δ. Solving Equation (12) for Δ and substituting the value obtained into Equation (32) gives,

$$v_y = \frac{\pi (f_y - s_y)}{\frac{L}{k}} \qquad (33)$$

Equation (33) gives the maximum value of the average shearing stress which the details are called upon to resist when the column is at its yield-point load, and, consequently, represents the desired basis for design.

When $\frac{L}{k} = 0$, $s_y = f_y$, and Equation (33) is seen to become indeterminate. To evaluate v_y for this case, $\frac{\Delta}{L}$ in Equation (32) may be made equal to the chosen ratio (for example, $\frac{\Delta}{L} = \frac{1}{400}$) for which Equation (32) becomes,

$$v = \frac{V}{A} = s\,\frac{\pi}{400}\,\frac{1}{1 - \frac{s}{s_e}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(34)$$

from which, the value of v_y for $\frac{L}{k} = 0$ is seen to be, $v_y = f_y\,\frac{\pi}{400}$.

It is interesting to note in this connection that while the effects of initial curvature and eccentricity of load on the bending stresses are approximately the same, this is not the case with regard to shearing stresses. Initial curvature is considerably more serious for shear, due to the fact that to begin with there is some definite slope at the end, while in the straight bar, eccentrically loaded, this slope at the end must be built up by the load.

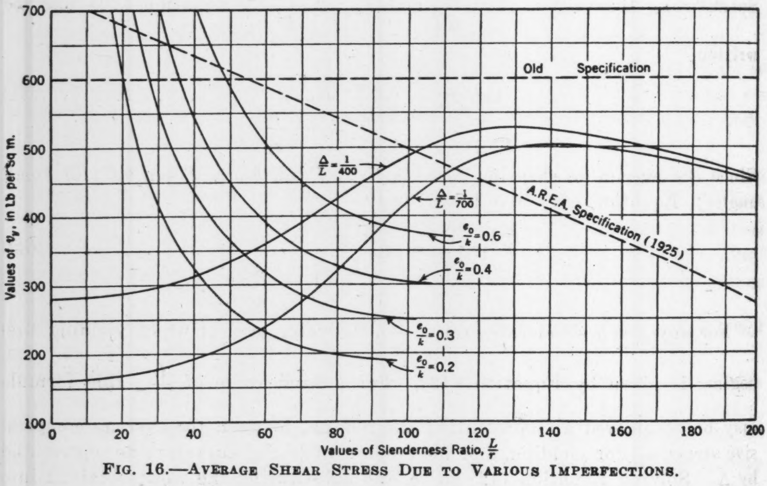

FIG. 16.—AVERAGE SHEAR STRESS DUE TO VARIOUS IMPERFECTIONS.

Taking values of s_y from the curves in Fig. 9, in which $k = r$, values of v_y may be computed from Equation (33) for various values of $\frac{L}{r}$, and any given ratio of $\frac{\Delta}{L}$. In this manner, curves may be plotted showing how the maximum average shearing stress, v_y, varies with the slenderness ratio, $\frac{L}{r}$, for any given ratio of $\frac{\Delta}{L}$. Such curves are shown in Fig. 16 for $\frac{\Delta}{L} = \frac{1}{400}$ and $\frac{\Delta}{L} = \frac{1}{700}$.

From an examination of these curves it is seen that the maximum shear occurs for columns having a slenderness ratio of about 130, which is greater than the usual allowance for slenderness made by specifications. For columns of the usual proportions the maximum average shearing stress varies from about 300 to 550 lb per sq in. in the case of the more severe allowance for imperfections. In Fig. 16, for purposes of comparison, a curve is shown which represents the A.R.E.A. Specifications of 1925 and a curve representing an older A.R.E.A. Specification. It might be judged that the new specification was unsafe for slender columns, but it must be remembered that this same specification limits the slenderness ratio of main compression members to 100 or less.

7.—SHEAR DUE TO IMPERFECTIONS REPRESENTED BY ECCENTRICITY

Considering imperfections represented in the form of eccentricity of load, as shown in Fig. 15 (*d*) and proceeding in the same manner as in the previous case (Section 6), the maximum angle, θ, at the middle cross-section is given by the equation:

$$\tan \theta_m = \frac{e}{L}\left[\frac{qL}{\sin \frac{qL}{2}} - 2\right] \qquad (35)$$

The maximum shearing force at the middle cross-section is,

$$V = \frac{2Pe}{L} + P \sin \theta \qquad (36)$$

Remembering that, for small angles, $\tan \theta = \sin \theta$, and substituting Equation (35), Equation (36) becomes,

$$V = \frac{Pe}{L}\left[\frac{qL}{\sin \frac{qL}{2}}\right] \qquad (37)$$

which gives the maximum shearing force for any value of the load.

It is interesting to note in connection with Equation (37) that $\frac{2Pe}{L}$ represents the shearing force at all cross-sections if deformation of the bar is neglected. Assuming that $q = \sqrt{\frac{P}{EI}}$ is very small, the term in the brackets in Equation (37) becomes equal to 2. However, as the load, P, is increased, this factor increases until when P reaches the Euler value it becomes equal to π. That is, for slender columns, where the load may reach the Euler value before the maximum fiber stress reaches the yield point, the shearing force may become 57% greater than the value that would be obtained by neglecting deformations.

Considering Equation (37) again, and dividing both sides by A, will give:

$$v = s\,\frac{e}{L}\left(\frac{qL}{\sin \frac{qL}{2}}\right) \qquad (38)$$

In this case where the effect of imperfections is being represented by the particular type of eccentricity represented in Fig. 15(*d*), it will be more reasonable to use a constant value of e than to take it as a function of the length, since for a short column there is just as much chance for accidental eccentricity of load as for a long one.

For this case, $a = -1$, and the value of s at which yielding begins, is given by Equation (19). Solving Equation (19) for the eccentricity, e, and substituting the value obtained into Equation (38) gives,

$$v_y = \frac{f_y - s_y}{\frac{L}{k}} \left(\frac{qL}{\sin \frac{qL}{2}} \right) \ldots\ldots\ldots\ldots\ldots\ldots (39)$$

Comparing Equation (39) with Equation (33), it is seen that for slender columns they give about the same result. However, for short columns, Equation (39) may give considerably higher values for the average shearing stress.

In Fig. 16 are shown four curves plotted from Equation (39), assuming an extreme I-section ($k = r$), for eccentricity ratios, $\frac{e}{k} = 0.2, 0.3, 0.4$, and 0.6. From a general study of all the curves in Fig. 16, a constant allowance for shearing stresses of 600 lb per sq in., in accordance with the old A.R.E.A. Specifications, would seem to be justifiable.

8.—SHEAR IN THE GENERAL CASE OF ECCENTRIC LOADING

Shear Stress at Yield-Point Load.—From an examination of the curves in Fig. 16 for equal eccentricities on opposite sides of the axis, it is seen that, for short columns, the shear arising due to such loading may be considerable. In the case of short stocky members in rigid frame construction, where large secondary end moments may arise, it seems advisable to know something about the possible extent of such shearing forces. The brief analysis[18] made herein will be for the equivalent case of eccentric loading, as considered in Section 4.

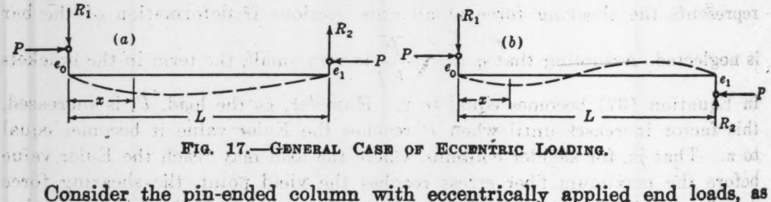

FIG. 17.—GENERAL CASE OF ECCENTRIC LOADING.

Consider the pin-ended column with eccentrically applied end loads, as shown in Fig. 17. The eccentricity, e_o, is taken as the larger so that in Fig. 17(*a*), $a = \frac{e_1}{e_0} > 0$, and in Fig. 17(*b*), $a = \frac{e_1}{e_0} < 0$. By the ordinary procedure the slope of the elastic line at any point, distant x from the left end, is found to be:

---

[18] For a detailed analysis, see the writer's paper, "Shearing Stresses in Steel Columns," *Publications*, International Assoc. for Bridge and Structural Eng., Vol. II, Zurich, 1934, p. 480.

$$\frac{dy}{dx} = -q\,e_0 \sin q\,x + q\,e_1 \frac{\cos q\,x}{\sin q\,L} - q\,e_0 \frac{\cos q\,x}{\tan qL} + \frac{e_0}{L} - \frac{e_1}{L} \quad \ldots\ldots(40)$$

For $\alpha > 0$ (Fig. 17(a)) the maximum shearing force will occur at the end of the column where $x = L$, and will be:

$$V = \frac{P\,(e_0 - e_1)}{L} + P\left[\frac{dy}{dx}\right]_{x=L} \quad \ldots\ldots\ldots\ldots\ldots\ldots(41)$$

For $\alpha < 0$ (Fig. 17(b)), the maximum shearing force will occur at the inflection point some place within the column and will be,

$$V = \frac{P\,(e_0 - e_1)}{L} + P\left[\frac{dy}{dx}\right]_{\max} \quad \ldots\ldots\ldots\ldots\ldots\ldots(42)$$

Substituting the values of $\left[\frac{dy}{dx}\right]_{x=L}$ and $\left[\frac{dy}{dx}\right]_{\max}$ into Equations (41) and (42), respectively, and dividing through by A, gives:

For $\alpha > 0$:

$$v = s\,\frac{e_0}{L}\,\phi\,\beta\,\csc\phi \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(43)$$

and for $\alpha < 0$:

$$v = s\,\frac{e_0}{L}\,\phi\,\psi\,\csc\phi \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(44)$$

in which, $\phi = q\,L = \frac{L}{r}\sqrt{\frac{s}{E}}$; $\beta = 1 - \alpha\cos\phi$; and $\psi = \sqrt{\alpha^2 - 2\,\alpha\cos\phi + 1}$.

For any given value of $\alpha = \frac{e_1}{e_0}$ the average shearing stress may be computed from Equation (43), or Equation (44), for any values of s and e_0.

It is desired to evaluate this average shearing stress for the particular load that first produces yielding in the extreme fibers. The corresponding values of s_y are given by Equations (19) and (22), in Section 4. Solving these formulas for e_0 and substituting the values obtained into Equations (43) and (44) gives:

$$v_y = \frac{(f_y - s_y)\,F}{\frac{L}{k}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(45)$$

in which, F is a numerical factor as follows:

For $\alpha > 0$, and $P < P_q$:

$$F = \phi\,\beta\,\csc\phi \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(46)$$

For $\alpha > 0$, and $P > P_q$:

$$F = \frac{\phi\,\beta}{\psi} \qquad \text{(47)}$$

For $\alpha < 0$, and $P < P_q$:

$$F = \phi\,\psi \csc \phi \qquad \text{(48)}$$

and for $\alpha < 0$, and $P > P_q$:

$$F = \phi \qquad \text{(49)}$$

Assuming an extreme I-section ($k = r$), and a steel for which $f_y = 36\,000$ lb per sq in, curves similar to Fig. 18 may be plotted from Equation (45), showing v_y as a function of the slenderness ratio for various values of α and $\frac{e_o}{k}$. Such curves may reasonably be used as a basis for the design of lacing or batten-bars in the case of short compression members in rigid frame construction, by using the secondary end moments, calculated in the usual approximate manner, to determine values of α and e_o.

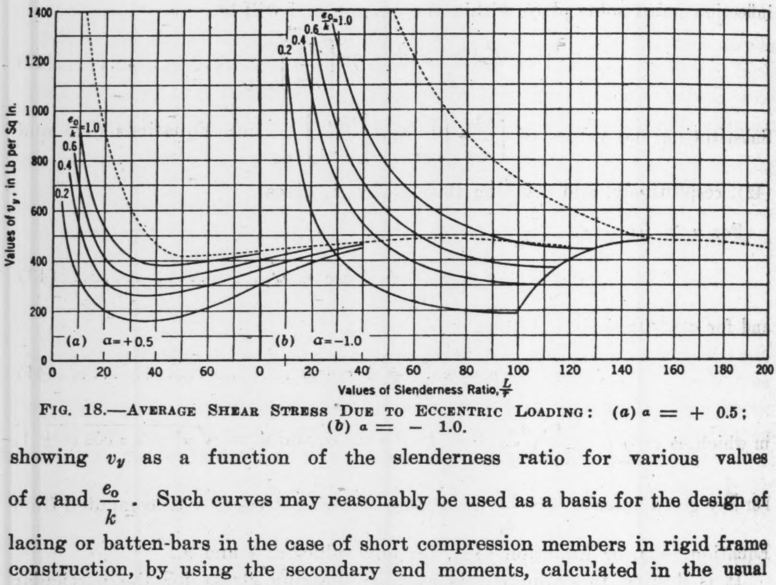

FIG. 18.—AVERAGE SHEAR STRESS DUE TO ECCENTRIC LOADING: (a) $\alpha = +0.5$; (b) $\alpha = -1.0$.

Absolute Maximum of Shear Stress.—From Equation (43) and (44), it is evident that, for a given slenderness ratio, there will be a particular combination of load and eccentricity (to produce yielding) for which the average shearing stress will be an absolute maximum. Since the eccentricity, e_o, has already been expressed in terms of the load in Equation (45), this equation may now be differentiated with respect to s and the derivative set equal to zero, to determine s as a criterion for absolute maximum shear. This procedure yields the following criteria for determining s:

For $\alpha > 0$, and $P < P_q$:

$$\frac{f_y - 3\,s}{f_y - s} = \phi \left[\cot \phi - \frac{\alpha \sin \phi}{\beta} \right] \qquad \text{(50)}$$

For $\alpha > 0$, and $P > P_q$:

$$\frac{f_y - 3\,s}{f_y - s}\,\alpha\,\phi\,\sin\,\phi\left[\frac{1}{\psi^2} - \frac{1}{\beta}\right] \dots\dots\dots\dots\dots\dots (51)$$

For $\alpha < 0$, and $P < P_q$:

$$\frac{f_y - 3\,s}{f_y - s} = \phi\left[\cot\,\phi - \frac{\alpha\,\sin\,\phi}{\psi^2}\right] \dots\dots\dots\dots\dots\dots (52)$$

and for $\alpha < 0$, and $P > P_q$:

$$s = \frac{f_y}{3} \dots\dots\dots\dots\dots\dots\dots\dots\dots\dots\dots (53)$$

Equations (50) to (53) may be solved graphically and the resulting s - criteria for absolute maximum shear shown by dotted curves such as those in Fig. 12.

When the criteria call for $s = 0$ (Fig. 12) this must be interpreted as meaning an infinitely small axial force at an infinitely large eccentricity. In other words, for short columns, bending by reverse couples at the ends is the worst possible type of loading for shearing stresses. It is interesting to note that for the particular steel chosen ($f_y = 36\,000$ lb per sq in.), these curves intersect the Euler curve at $\frac{L}{r} = 157$. This means that in the case of slender columns the worst possible type of loading for shear is an axial load without any eccentricity. For the intermediate columns the criteria require some combination of thrust and bending to produce the worst conditions for shear.

Using the values of s from these curves in Equation (45), the curves of absolute maximum shear for the various values of α considered, have been plotted in Fig. 18. In each diagram, this curve of absolute maximum shear stress is shown by the dotted line.

The absolute maximum shear runs fairly high, especially for negative values of α. Therefore, in the case of short compression members in rigid frames, it would seem more advisable to use the actual values of e_o and α obtained by secondary stress calculations in determining the shear stress, than to try to make some blanket allowance for all cases. The usual additional allowance for the effect of imperfections should be made in the same manner as outlined in Section 4. In this case, however, eccentricities on opposite sides of the axis to represent imperfections would be superposed on the actual eccentricities, e_o and e_1, to give the modified values to be used in determining α.

ACKNOWLEDGMENT

The writer is particularly indebted to Professor S. Timoshenko, of the University of Michigan, for invaluable help and advice in the preparation of this paper.

SUMMARY

Although, in this paper, the writer does not pretend to solve, completely, the problem of column design, he offers what is believed to be a more logical basis of procedure than is represented by present-day practice. It is recommended that, as a basis of calculation, some imperfection in the form of an initial curvature or eccentricity of load be taken, and then that the working load be selected on a basis of the load first producing yielding in the extreme fibers due to the assumed form of imperfection.

For pin-ended columns the final proposal for a basis of design is represented by the curves for $\Delta = \frac{L}{400}$ in Fig. 9. For columns in rigid frame construction, in which secondary end moments arise due to the rigidity of the joints, it is proposed to use a set of curves such as those illustrated by Fig. 12 as a basis of design, in which the values of a and e_o will be determined by the usual approximate method of calculating secondary stresses.

For pin-ended columns, which are built up with lacing or battens, an average shearing stress of 600 lb per sq in. is proposed as a basis for the design of the lacing or battens.

For built-up columns in rigid frame construction, it is proposed to use curves such as as those presented in Fig. 18, as a basis for the design of lacing and battens, in which the values of a and e_0 will be found from the secondary stress calculations.

APPENDIX

NOTATION

The following symbols conform as nearly as practicable with the "Symbols for Mechanics, Structural Engineering, and Testing Materials", advanced by the American Standards Association[4]. Some of the symbols do not appear in the paper, but are included herein, as a matter of information:

a = distance, center to center, of column stiffeners (batten-plates or lattice-bars); also, a = unsupported length of channels. As a subscript, a denotes "average".

b = distance between gravity axes of channels; as a subscript, b denotes "batten-bars".

c = distance from neutral axis to extreme fiber; as a subscript, c denotes "critical".

d = depth; as a subscript, d denotes "diagonal bars".

e = initial eccentricity of load; as a subscript, e denotes "Euler".

f = unit stress; f_y = yield-point stress.

i = any integer; as a subscript, i denotes 'initial".

k = core radius of a cross-section $= \frac{S}{A}$.

m = Poisson's ratio; as a subscript, m denotes "maximum".

n = a factor of safety.

q = a substitution factor $= \sqrt{\frac{P}{EI}}$; as a subscript, q denotes "a certain value".

r = radius of gyration $= \sqrt{\frac{I}{A}}$.

$s = \frac{P}{A}$ = average compressive stress on the column; s_y = average compressive stress at which yielding in the extreme fibers first begins; s_w = allowable working stress; $s_e = \frac{\pi^2 E}{\left(\frac{L}{r}\right)^2}$ = stress corresponding to the Euler load; and s_q = a certain value of s.

t = thickness.

v = average shearing stress, $\frac{V}{A}$; v_y = average shearing stress when Load P is at its yield-point value.

w = load per unit distance; as a subscript, w denotes "working load".

x = variable co-ordinate of Deflection y.

y = deflection of a column, distant x from one end; y_o = initial deflection of a deflected column; as a subscript, y denotes "yield point".

A = area; A_d = cross-sectional area of two diagonal bars; A_b = cross-sectional area of two batten-bars.

C = a constant to be evaluated from the end conditions of a bar.

E = modulus of elasticity.

F = a numerical factor (Equation (45)).

G = shearing modulus for batten-plates.

I = rectangular moment of inertia with respect to gravity axis of bending; $I_c = I$ for one channel, about its gravity axis; $I_b = I$ of two batten-plates with respect to gravity axis of bending.

K = a coefficient = 1.2 for rectangular batten-plates.

L = length; L' = a fictitious column length.

M = bending moment; M_o and M_1 = secondary end moments.

P = compressive axial load on a column; P_e = the Euler load for a pin-ended column $= \frac{\pi^2 EI}{L}$; P_c = critical load for any column; P_y = load that first produces yielding, due to eccentricity; P_w = allowable working load.

S = section modulus.

V = total shear force at any cross-section.

W = total load.

α = a ratio, $\frac{e_1}{e_0}$.

$\beta = 1 - \alpha \cos \phi$.

Δ = maximum initial deflection of an initially curved column.

θ = an angle (Fig. 16).

π = 3.1416.

$\phi = q\,L = \frac{L}{r}\sqrt{\frac{s}{E}}$.

$\psi = \sqrt{\alpha^2 - 2\,\alpha \cos \phi + 1}$.

ω = angle between batten-bar and diagonal bar.

DISCUSSION

WILLIAM R. OSGOOD,[17] M. AM. SOC. C. E. (by letter).—Since the design of compression members which would fail by buckling, if they failed, is admittedly the element in structural design least satisfactory to handle, any paper that again brings to the attention of engineers the intrinsic difficulties involved is worth while.

Mr. Young does well to call attention to the collection of column curves in the A. I. S. C. Manual,[3] for hardly a better exhibit exists showing the (unavoidable) uncertainty of engineers concerning the strength of columns used in ordinary structures. The very existence of such a large "factor of uncertainty" among qualified engineers calls for the assumption of a correspondingly large factor of safety.

It is well known that the strength of medium-long columns is affected markedly by small eccentricities or initial curvatures. Mr. Young is concerned chiefly with such accidental departures from ideal conditions, and he proposes, as has been done time and again, to assume values for these quantities, which are quite unknown in an actual structure, and then to design on the basis of maximum fiber stress. This procedure, as has also been pointed out before, is merely a method of applying a variable factor of safety. It is not a very good method because it results in excessive safety for short columns, as Fig. 8 indicates, and it makes the H-section appear stronger than the rectangular section, as Figs. 9 and 10 indicate, whereas the H-section is actually the weakest of all symmetrical cross-sections.[18] The inherently safest columns so far as the effects of accidental departures from ideal conditions are concerned are, on the one hand, very short columns in which, if failure occurs, the material itself fails, and buckling plays no part, and, on the other hand, very long columns which, if they fail, fail by pure buckling, and in which high strength of the material is of no consequence.

It cannot be emphasized too strongly that the strengths of columns, except very short ones, do not depend on any one particular stress, such as the yield point, or any other. The strength depends on the compressive stress-strain diagram as the double-modulus theory of column action shows.

Mr. Young speaks of the proportional limit in the same breath with yield point and ultimate strength, yet while the last two stresses are readily, and fairly definitely, determinable, the proportional limit may be obtained as any stress from almost zero to nearly the yield point, depending on who does it and how he does it. For practical purposes in the design of columns the highest stress for which Euler's formula applies may be considered as the proportional limit. This stress will be well above a proportional limit carefully determined from a difference curve but also well below the yield point of most structural steels. It is entirely unjustifiable, therefore, to assume the ideal stress-strain diagram of Fig. 2 in explaining the behavior of columns, except possibly at large values of the eccentricity ratio. The whole problem of column action is indeed simplified on the assumption of such a diagram; in fact, there is little left, for it is precisely in the range of stresses between the highest stress for which Euler's formula is applicable and the yield point that the action of columns is most erratic.

[18] *Civil Engineering*, March, 1935, p. 173.

ALFRED S. NILES,[19] ASSOC. M. AM. SOC. C. E. (by letter).—The formulas developed in Section 4 to determine the maximum stress in cases of eccentric loading are not as convenient for practical use as the equivalent ones that can be derived from the same basic theory. In the case of a member with axial compression and end moments, but no transverse load, the distance, x_m, from the left end of the span to the point of maximum moment is given by the formula[20] (using the author's notation):

$$\tan q\, x_m = \frac{e_1 - e_0 \cos \phi}{e_0 \sin \phi} \quad \ldots\ldots\ldots\ldots\ldots\ldots (54)$$

Equation (54) gives the location at which the slope of the moment curve is zero. If $e_0 > e_1$ and $\tan q\, x$ is negative, this point will be off the span, and the true maximum moment will be that at the left support. If $\tan q\, x$ is positive, the maximum moment will be on the span, and its magnitude will be:

$$M_m = \frac{P\, e_0}{\cos q\, x_m} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (55)$$

In practice, it is quite as easy to apply the criterion of the sign of $\tan q\, x_m$ as to use Equation (18) or Equation (24). If it is then found that the maximum moment is in the span, it is easier to find the secant or cosine of an angle, the tangent of which is known, than to compute the quantity, ψ, which appears in Equations (21) and (25). If this line of attack is followed, Equation (25) would be superseded by,

$$M_m = M_0 \sec q\, x_m = \frac{M_0}{\cos q\, x_m} \quad \ldots\ldots\ldots\ldots\ldots\ldots (56)$$

and Equation (22) by,

$$s_y = \frac{f_y}{1 + \dfrac{e_0}{k \cos q\, x_m}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (57)$$

The forms with the cosine are usually more convenient than those with the secant because tables of the former function are more common. If the cosine, $q\, x_m$, is very small, however, it is better to compute the secant directly from the relation, $\sec^2 x = \tan^2 x + 1$.

Just as the computation for maximum moment can be simplified by making the determination of the location of that moment a step in the computation, so can the computation of maximum shear. The expression for the total shear at any point distant x from the left end of an eccentrically loaded strut can be written,[20]

$$V = P \left[\frac{e_1 - e_0 \cos \phi}{\sin \phi}\, q \cos q\, x - e_0\, q \sin q\, x \right] \ldots\ldots\ldots (58)$$

---

[19] Prof. of Aeronautic Eng., Stanford Univ., Stanford University, Calif.

[20] "Airplane Structures," by Niles and Newell, John Wiley & Sons, 1929, p. 201.

The slope of the shear curve will be zero when,

$$\cot q\, x_s = -\frac{e_1 - e_0 \cos \phi}{e_0 \sin \phi} \quad \text{(59)}$$

When $\alpha = \frac{e_1}{e_0}$ is positive, Equation (59) will indicate a location that is off the span, and the maximum shear will be at the right-hand end of the span (assuming $e_1 < e_0$). Its magnitude divided by the area of the section will be,

$$v = \frac{V}{A} = s\, e_0\, q\, (1 - \alpha \cos \phi) \csc \phi = s\, e_0\, q\, \beta \csc \phi \quad \text{(60)}$$

When α is negative, the shear stress at the point of inflection is given by,

$$v = s\, q\, e_0 \csc q\, x \quad \text{(61)}$$

Equations (60 and (61) can be proved to be identical with Equations (43) and (44), and are much easier to use.

Continuing along the same lines, Equations (45) to (49), inclusive, can be replaced by,

$$v_y = k\, q\, (f_y - s_y)\, F \quad \text{(62)}$$

in which, F is a numerical factor, as follows: For $\alpha > 0$ and $M_{\max}$ at $x = 0$:

$$F = (1 - \alpha \cos \phi) \csc \phi = \beta \csc \phi \quad \text{(63)}$$

for $\alpha > 0$ and $M_{\max}$ at $x = x_m$:

$$F = (1 - \alpha \cos \phi) \csc \phi \cos q\, x_m = \beta \csc \phi \cos q\, x_m \quad \text{(64)}$$

for $\alpha < 0$ and $M_{\max}$ at $x = 0$:

$$F = \csc q\, x_s = \sec q\, x_m \quad \text{(65)}$$

and, for $\alpha < 0$ and $M_{\max}$ at $x = x_m$:

$$F = 1 \quad \text{(66)}$$

It is to be noted that Equation (63) is a special case of Equation (64) for $x_m = 0$. The criteria for absolute maximum shear represented by Equations (50) and (53) remain unchanged, but Equations (51) and (52) may be replaced by,

$$\frac{f_y - 3\, s}{f_y - s} = \phi \left[\cot \phi - \frac{\alpha \sin \phi}{\beta} \right] + q\, x_m \tan q\, x_m \quad \text{(67)}$$

and,

$$\frac{f_y - 3\, s}{f_y - s} = -\, q\, x_m \tan q\, x_m \quad \text{(68)}$$

Equations (54) to (68) would be more convenient for plotting curves such as those of Figs. 12, 16, and 18, than the corresponding equations in the author's paper. The first step in the analysis of an eccentrically loaded strut would be the determination of the location of the point of zero slope of the moment curve from Equation (54). The distance from this point to the point of inflection, multiplied by q, will be $\frac{\pi}{2}$. It can then be seen which of the four cases is represented. Some saving of time can probably be obtained by taking advantage of the relations between Equations (63) and (64) and Equations (50), (67), and (68).

Similar formulas for locating the point of maximum moment, etc., can easily be derived for cases of axially loaded beams. Formulas for the total shear, bending moment, slope, and deflection for single span, and continuous beams of this type, with various types of transverse load, based on the work of Müller-Breslau, have been published by the writer.[21]

In the text following Equation (22), the author recommends the addition of assumed eccentricities to allow for imperfection of manufacture. When the known eccentricity, e_1, is of the same sign as e_0, it is obvious that assumed eccentricities should be added. The author might have brought out more clearly that when e_1 and e_0 are of opposite sign the assumed eccentricities should be added algebraically rather than arithmetically. Only in this way will the assumed value of the distance from the left end to the point of inflection be increased, as is necessary if the correction is to be on the conservative side.

Although some of the author's formulas could be simplified, his basic ideas and his developments from them are sound, making his paper a valuable contribution to the literature of column theory.

J. F. BAKER,[22] ASSOC. M. AM. SOC. C. E. (by letter).—Many of the methods used to-day for the design of compression members are so unsatisfactory that any paper advocating a rational approach should be carefully studied by all structural engineers. Mr. Young's attack of the problem is most sound and he may be interested to know that certain of his suggestions have already been put into practice.

His proposal to take a definite initial curvature of the axis of the member to represent all imperfections, find the load that first produces the yield stress, and then to divide this load by a constant factor to arrive at the working load was used in deriving the strut formula contained in the Steel Structures Research Committee's Recommendations for a Code of Practice for the Use of Structural Steel in Buildings, published in 1931.[23] These recommendations were adopted by the London County Council and also by the British Standards Institution, the formula being included in the London County Council's revised Code of Practice, for the design of buildings erected in London, which came into force on February 16, 1932, and in the British Standard Specification (No. 449) for the Use of Structural Steel in Buildings published in April, 1932. Thus, for the last three years almost all stanchions of steel framed buildings erected in Great Britain and many other parts of the world have been designed on this rational basis. The formula,

[23] First Rept., Steel Structures Research Committee, Lond., H. M. Stationery Office, London, England, 1931.

$$n\,f = \frac{f_y + (\eta + 1)\,\epsilon_e}{2} - \sqrt{\frac{f_y + (\eta + 1)\,\epsilon_e}{2} - f_y\,\epsilon_e} \;\ldots\ldots\ldots(69)$$

in which (following the notation of the paper), f = working stress, in tons per square inch of gross section; n = factor of safety = 2.36; f_y = yield-point stress = 18 tons per sq in.; ϵ_e = the Eulerian value, $\dfrac{\pi^2 E}{\left(\dfrac{L}{r}\right)^2}$, in tons per square inch; and $\eta = 0.003\,\dfrac{L}{r}$. Equation (69) is merely a convenient form of the Perry formula[24] for the maximum stress in an initially curved, pin-ended, compression member which has been derived by Mr. Young as Equation (13). The measure of the initial curvature, η, was adopted as a result of Professor Andrew Robertson's study[25] of a large number of tests on struts, whereas the factor, 2.36, was chosen from a consideration of existing strut formulas.

The Recommendations for a Code of Practice were published shortly after the Committee's inception and were only tentative. As the work involved was very lengthy, it was found impossible at the time to include a rational rule for the design of stanchions subjected to end bending moments. It would have been useless to provide the designer of a steel framed building with a strut formula that necessitated the accurate determination of the end moments since in the state of knowledge then existing it was impossible to estimate, with any accuracy, the moments transmitted from the beams through the steelwork connections. As Mr. Young states, the labor involved is considerable, but in the four years since 1931 a number of investigators working for the Steel Structures Research Committee have concentrated on the problem and their work has been under consideration for some months. While it is not possible to state exactly what the Committee's final findings will be, it is probable that design curves will be produced having the same basis as set forth by Mr. Young and applicable to stanchion lengths subjected to end moments.

Some indication of the argument which is being followed can be obtained from a paper[26] in the Committee's interim report. In that paper a method is given of dealing with an initially curved strut subjected to unequal end moments, which covers much the same ground as that of Section 4 in Mr.

Young's paper. The method is interesting in that it uses a graphical construction due to Mr. H. B. Howard.[27]

For example, in Fig. 19, draw Lines *OA* and *OB* through the pole, *O*, in such a manner as to make equal angles, $\theta = \frac{L}{2}\sqrt{\frac{P}{EI}}$, with the center line, *OZ*. These lines are made to represent M_a and M_b to some definite scale, being measured upward from *O* for positive moments. A circle, *BXAO* (Fig. 19), is constructed through Points *B, O,* and *A*. The bending moment at Point *N* on the beam, distant *x* from the center line, is then represented by the vector, *ON*, which is drawn so that $< NOZ = x\sqrt{\frac{P}{EI}}$. The maximum bending moment in the beam is given by the length of the diameter, *OX*.

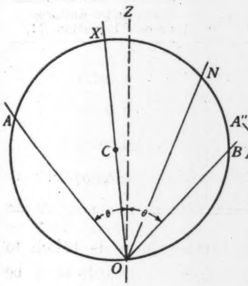

FIG. 19.

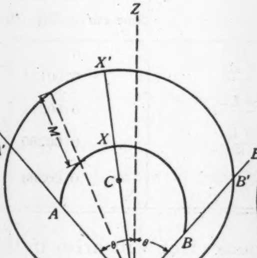

FIG. 20.

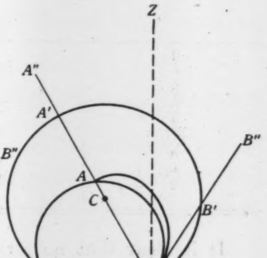

FIG. 21

Before this construction can be used for a practical column some method of allowing for the initial curvature representing the imperfections of the member must be found. It is most usual to assume the initial shape to be that of a sine curve; there is nothing axiomatic, however, about that curve, and the stresses in the column would not be seriously affected by a slight change in its initial shape. Table 1 gives a comparison between the sine curve,

[27] "The Graphical and Analytical Determination of Stresses in Single Span and Continuous Beams Under End Compression and Lateral Load with Variations in Shear, Distributed Load, and Moment of Inertia," by H. B. Howard, Reports and *Memoranda No. 1233*, Aeronautical Research Committee, Lond., H. M. Stationery Office, 1929.

$$y = 0.003 \frac{L r}{a} \sin \frac{\pi x}{L} \text{ ....(70)}$$

which is the initial curvature assumed in the Committee's formula (Equation (69)) and the shape assumed by an originally straight beam when subjected to a uniform moment, M, such that,

$$M = 0.024 \frac{r E I}{a L} \text{ ....(71)}$$

in which, a is the half width of the column and I is its moment of inertia.

TABLE 1.—COMPARISON OF SHAPES FOR INITIAL CURVATURE OF COLUMN

x		$y \frac{a}{L r}$	
		Sine curve, Equation (70)	Beam under uniform moment, Equation (71)
0	L	0	0
$\frac{L}{8}$	$\frac{7L}{8}$	0.00115	0.00131
$\frac{L}{4}$	$\frac{3L}{4}$	0.00212	0.00225
$\frac{3L}{8}$	$\frac{5L}{8}$	0.00280	0.00282
$\frac{L}{2}$	.....	0.00300	0.00300

It is clear that no serious error will arise if this latter shape is taken to represent the initial curvature of the column. Therefore, a graph may be constructed for the approximate bending moment at any point of an initially curved column subjected to end moments, M_a and M_b, as follows: Lines OA'' and OB'', Fig. 20, are drawn so that they make equal angles, $\theta \left(= \frac{L}{2} \sqrt{\frac{P}{EI}} \right)$, with the center line, OZ. Along these two lines, OA' and OB' are measured in such a manner that $OA' = M + M_a$ and $OB' = M + M_b$, in which, $M \left(= 0.024 \frac{r E I}{a L} \right)$ is the uniform moment necessary to produce the initial curvature in the column. The circle, A' X' B' O, in Fig. 20 gives the bending moment in an initially straight column subjected to end moments, $(M + M_a)$ and $(M + M_b)$; the bending moment required at any point of the initially curved column can be read from the figure, AXB, obtained from the circle, A' X' B', by subtracting the moment, M, from each vector. If Line OX' is a diameter of the circle, A' X' B' O, the maximum bending moment in the initially curved column will be given by the length of the intercept, OX.

It will be seen from Figs. 20 and 21 that when the center, C, of the circle, $A'OB'$, lies on Line OA'', or on Line OB'', or anywhere on the opposite sides of those lines from the position shown in Fig. 20, the maximum bending moment will be found at one end or other of the column. When this occurs the end moments will have completely masked the "strut action" and there seems to be no reason why the permissible stress in the column should be cut down below the value, 8 tons per sq in., allowed in a beam. The critical values of the end moments which make C lie on Line OA'' or on Line OB'' are, therefore, of considerable importance.

The critical values are given by,

$$\frac{M_b + M}{M_a + M} = \cos 2\,\theta \quad \text{.......................} (72)$$

in which, M_a and M_b are the applied end moments and,

$$M = 0.024\,\frac{r\,E\,I}{a\,L} \quad \text{.......................} (73)$$

The maximum bending moment in a column length, therefore, will occur at the end where the greatest end moment is applied when such moments have values defined by Equation (72); or when the greater end moment is M_a and the smaller is less than M_b; or, when the smaller end moment is M_b and the greater exceeds M_a.

In certain lengths of continuous columns a simple relation between the end moments may be assumed. For instance, in any length of an outside stanchion, except the bottom and topmost, the end moments due to dead load or to the worst combination of live loading are nearly equal in magnitude and opposite in sign, the sign convention being that of Figs. 19, 20, and 21. The critical value of the end moment is, therefore,

$$M_c = \frac{M\,(1 - \cos 2\,\theta)}{(1 + \cos 2\,\theta)} \quad \text{.......................} (74)$$

and it is a simple matter to calculate for any length of outside stanchion, having its axis, YY, in the plane of the outside wall and subjected to any axial load, the minimum value of the end moment that will ensure the maximum moment occurring at the end.

An examination of the measured stresses in existing steel framed buildings has shown that in many cases the maximum stress occurs at an end section of the column and, therefore, the permissible stress could be taken at the full value allowed in beams.

The foregoing analysis and that given by Mr. Young only refers to end moments which bend the member in the plane containing the initial curvature. The great majority of stanchion lengths have end moments about both principal axes, and it is essential that these should be taken into account in a practical design method. For a member bent into single curvature by end moments about both axes, all the information required is contained in Equation (75), in which the yield stress of the material is taken as 18 tons per sq in., the factor of safety is 2.36, and the allowance for initial curvature is the same as in Equation (69),

$$\begin{aligned}(7.63 - P)&\left[1 - \frac{2.36\,P}{\pi^2 E}\left(\frac{L}{rx}\right)^2\right]\left[1 - \frac{2.36\,P}{\pi^2 E}\left(\frac{L}{ry}\right)^2\right]\\ &= f_{x\text{-}x}\left[1 + \frac{0.61\,P}{\pi^2 E}\left(\frac{L}{rx}\right)^2\right]\left[1 - \frac{2.36\,P}{\pi^2 E}\left(\frac{L}{ry}\right)^2\right]\\ &\quad + f_{y\text{-}y}\left[1 + \frac{0.61\,P}{\pi^2 E}\left(\frac{L}{ry}\right)^2\right]\left[1 - \frac{2.36\,P}{\pi^2 E}\left(\frac{L}{rx}\right)^2\right]\\ &\quad + 0.003\,P\left(\frac{L}{ry}\right)\left[1 - \frac{2.36\,P}{\pi^2 E}\left(\frac{L}{rx}\right)^2\right] \quad \ldots\ldots\ldots\ldots(75)\end{aligned}$$

in which, P = axial load, in tons per square inch; $f_{x\text{-}x}$ = end bending stress about the major axis, XX, in tons per square inch; and $f_{y\text{-}y}$ = end bending stress about the minor axis, YY, in tons per square inch.

From this case, design curves can be produced with ease, but the procedure is somewhat more complicated than that usual in design offices to-day. Where this complication must be avoided it can be proved that safety in design is assured in all cases if a bending stress equal to the sum of the bending stresses, $f_{x\text{-}x} + f_{y\text{-}y}$, about both axes is assumed to be due to bending about the minor axis, YY, and the simpler design curves corresponding to that case are used. Considerable economy is sacrificed, however, by this simplification.

Mr. Young has mentioned the effect of the axial load in the member on the end moments. In steel framed buildings this effect of the axial load can be considered as arising from two causes: (*a*) The flexure brought about by loading the beams; and (*b*), the initial curvature. As far as the production of a safe design formula is concerned Cause (*a*) may be neglected in all cases; Cause (*b*) may be neglected when the column is bent by the beams in single curvature; but it must be taken into account when the bending is in double curvature. With the conservative allowance of initial curvature which must be made to represent the imperfections of the member, the effect may be considerably more than the 6% mentioned by Mr. Young for the modification of secondary end moments in trusses.

K. L. De Blois,[28] Assoc. M. Am. Soc. C. E. (by letter).—The subject of a rational design for steel columns, of course, is not a new one. A glance through engineering literature will show the attempt to derive a formula which is theoretical and at the same time not too difficult to apply from the designer's point of view. Mr. Young's derivation follows closely that of the well-known secant formula except that he assumes that the eccentricity is represented by an equivalent curvature, whereas the secant formula is based on an initial end eccentricity.

The author points out a serious defect in the column formulas of the straight-line, parabolic, and Rankine types in general use to-day. This defect is that the relation between the axial load and the maximum fiber stress is non-linear as shown in Fig. 6. In other words, if f_m is 30 000 lb per sq in., s_y is not 1.5 times the value of s_y when f_m is 20 000 lb per sq in. This is due to the change in eccentricity as P varies. The secant formula, Equation (14), with its transcendental function takes this into account as does the author's Equation (12). This means that if tension members of a structure were designed for a certain loading and a unit stress of 18 000 lb per sq in., they would all become stressed to 26 000 lb per sq in. under a 50% increase in load; whereas, in a compression member, if the load were increased 50% the unit stress would be greater than 26 000 lb per sq in. This is important because many bridge design specifications require that all truss members shall be uniformly stressed under a certain increase in the live load.[29]

---

[28] **Assoc. Highway Bridge Engr., U. S. Bureau of Public Roads, San Francisco, Calif.**

The term, $\frac{e}{k}$, in Equation (14) can be written $\frac{e\,c}{r^2}$ since $k = \frac{S}{A} = \frac{I}{c\,A} = \frac{A\,r^2}{c\,A} = \frac{r^2}{c}$. The formula is then in its usual form,

$$s = \frac{f_m}{1 + \frac{e\,c}{r^2} \sec\left(\frac{L}{2r}\sqrt{\frac{s}{E}}\right)} \qquad \text{.................(76)}$$

By substituting the term, $\left(1 + \frac{\left(\frac{L}{r}\right)^2}{X\left(\frac{c}{r}\right)}\right)$, for $\sec\left(\frac{L}{2r}\sqrt{\frac{s}{E}}\right)$, the resulting formula (termed the "Modified Secant Formula") follows the secant formula curve closely for values of $\frac{L}{r}$ less than 200[29]; thus:

$$s = \frac{f_m}{1 + \frac{e}{r}\left(\left(\frac{L}{r}\right)^2 \frac{1}{X} + \frac{c}{r}\right)} \qquad \text{.................(77)}$$

in which, X is a constant, its value depending on f_m. In railroad work a bridge is considered ready for renewal when f_m becomes 26 000 lb per sq in. Using this value of f_m in the secant formula (Equation (76)), the modified secant formula is,

$$s = \frac{26\,000}{1 + \frac{e}{r}\left(\left(\frac{L}{r}\right)^2 \frac{1}{6\,400} + \frac{c}{r}\right)} \qquad \text{................(78)}$$

If the working stress, f_w, is 20 000 lb per sq in., Equations (76) and (78) would be divided by 1.3 to get the design unit stress. This gives slightly larger sections than by using f_m of 20 000 lb per sq in. in Equation (76), but the compression members would then be stressed consistently with the tension members when the load is increased 1.3 times. Thus, Equations (77) and (78) need not be solved by "trial and error" as in the case of the author's equations. It must be understood, however, that the non-linear relation between f_m and s is attained by varying the value of X in Equation (77) to fit the secant formula, (Equation (76), as different values are used for f_m. For design purposes where one or two values are used for f_m, Equations (77) and (78), providing a direct solution, are more desirable. However, in research and investigation work where different values of f_m are encountered, Equation (12) is certainly easier to solve than the secant formula, Equation (76).

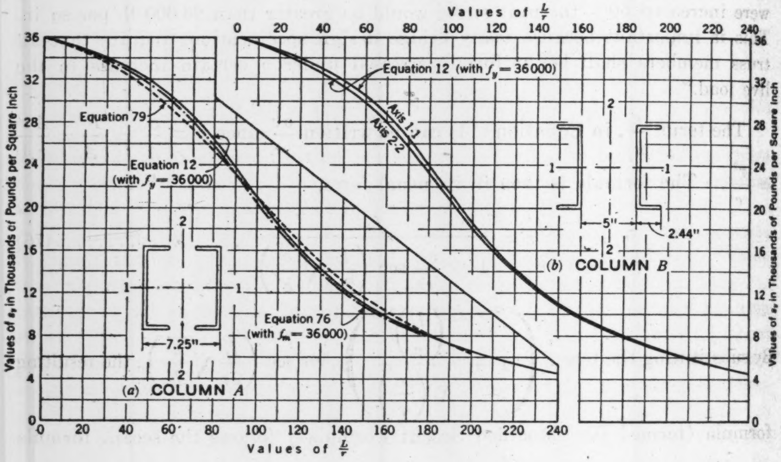

FIG. 22.—EFFECT OF $\frac{L}{r}$ -RATIO ON s_y.

A comparison of the author's equations with the modified secant formulas for two different column sections, is shown in Fig. 22. The column characteristics are shown in Table 2. Let f_y = 36 000 lb per sq in.; let e and Δ both be assumed as $\frac{L}{750}$; E = 29 000 000; and X in the modified secant formula = 2 500. Then Equation (77) becomes,

TABLE 2.—CHARACTERISTICS OF COLUMNS IN FIG. 22 (TWO 8-INCH CHANNELS @ 16.25 POUNDS)

Definition	FIG. 22 (a)		FIG. 22 (b)	
	Axis 1–1	Axis 2–2	Axis 1–1	Axis 2–2
(1)	(2)	(3)	(4)	(5)
Section area, A, in square inches	9.52	9.52	9.52	9.52
Moment of inertia, I, in inches ^{4}	79.6	92.7	79.6	92.7
Radius of gyration, r, in inches	2.89	3.10	2.89	3.10
Distance, c, from neutral axis to extreme fiber, in inches	4.00	3.62	4.00	4.94
Ratio, $\frac{c}{r}$	1.39	1.17	1.39	1.59
r^2	8.35	9.61	8.35	9.61
$k = \frac{r^2}{c}$	2.09	2.65	2.09	1.95

$$s_y = \frac{36\,000}{1 + \frac{e}{r}\left(\left(\frac{L}{r}\right)^2 \frac{1}{2\,500} + \frac{c}{r}\right)} \quad \ldots\ldots\ldots\ldots\ldots (79)$$

$$\frac{\Delta}{k} = \frac{L}{750} \times \frac{c}{r^2} = 0.00133\left(\frac{L}{r}\right)\left(\frac{c}{r}\right) \quad \ldots\ldots\ldots\ldots (80)$$

and,

$$\frac{e}{r} = \frac{L}{750} \times \frac{1}{r} = 0.00133\,\frac{L}{r} \quad \ldots\ldots\ldots\ldots\ldots\ldots (81)$$

Another marked improvement in the author's formula is the term, $\frac{\Delta}{k}$, which takes into account the shape of the column. Since $k = \frac{S}{A} = \frac{r^2}{c}$, $\frac{\Delta}{k}$ may be written $\frac{\Delta\, c}{r^2}$, or $\frac{\Delta}{r} \times \frac{c}{r}$. The importance of this "eccentricity ratio," $\frac{\Delta\, c}{r^2}$ — and more particularly, $\frac{c}{r}$ — cannot be over-emphasized. It has generally been assumed that if the column section were such that the radius of gyration, r, is the same about either axis the column would have the same strength; but this is not the case unless the ratio, $\frac{c}{r}$, is the same about both axes.[29]

The columns in Fig. 22 have the same minimum radius of gyration, r, but the ratio, $\frac{c}{r}$, for the column in Fig. 22(*b*) changes the limiting axis and is weaker than the column in Fig. 22(*a*). Present-day formulas would lead to the conclusion that the columns were equal in strength since their minimum radii of gyrations are equal; but the secant formula shows that this is not true. The limiting axis of the column in Fig. 22(*b*) is 2–2 even though the radius of gyration, r, is greater than about Axis 1–1. Without regard to formulas one would expect the outstanding legs of Column B to be a source of weakness. Thus, the secant type of formulas enables the designer to take into account the column shape as accurately as he now computes the radius of gyration. The most economical section occurs when $\frac{c}{r}$ is a minimum about either axis. It approaches 1.00 as a minimum. A circular section, of course, would be the nearest approach to the ideal. The $\frac{c}{r}$-ratio has a marked effect on s for values of $\frac{L}{r}$ from 20 to 80, a common range in design. A variation in $\frac{c}{r}$ from 1.5 to 2.5 affects the values of s as much as a variation of $\frac{L}{r}$ from 40 to 60 or from 60 to 80.

The total effect of $\frac{c}{r} \times \frac{e}{r}$ is given by the author's use of $\frac{\Delta}{k}$, but in so doing the real significance of the $\frac{c}{r}$-ratio is lost. In applying the author's Equation (12) the ratio, $\frac{c}{r}$, appears as in Equation (80). It is best, however, to keep the $\frac{c}{r}$-ratio separate as a guide in choosing the column section.[30]

Referring to Fig. 22 the maximum variation of Equations (77) to (81) from those of the author is about 1 000 lb per sq in. With a value of n equal to 2.25 this would be only 440 lb per sq in. On Fig. 22(*b*) is shown the secant formula for Column *A*, Axis 1–1, only. The values of s are slightly less than those given by the author's formula and in close agreement with the Hunley formulas for $\frac{L}{r}$ less than 200.

The important point is that these formulas, although giving slightly different results, have the characteristics of a rational column formula, namely (1) when e or $\Delta = 0$, $s = f$; (2) they express the non-linear relation between s and f; and (3) they take into account the shape of the column as well as the slenderness ratio.

Marvin A. Gray, Esq.[31] (by letter).—Long before Samson and Delilah, which is more than 3 000 years ago, columns have played an important part in tragedies. Any study of the structures of ancient times, as far back as records go, shows that an inherent subconscious fear of the combined features of lack of strength and stability in columns existed. This can be observed readily in the pictures of ancient buildings. The ancients built their columns by what they thought was a rational method of design; and yet many workmen were killed in the construction of their larger buildings and bridges. On August 29, 1907, the Quebec Bridge collapsed, one of the world's greatest structural failures; to-day, tragedies of column failure occur even in airplanes, which are more carefully and exactly designed than any other structure built. Therefore, this paper is on a most useful subject, presented at an opportune time; but it touches only lightly on the subject.

With the coming of Galileo there is record of a definite beginning in the development of the structural theory. Then came Hooke and Huygens with their conception of elasticity. In 1696 Jacques Bernoulli[32] proposed the problem[33] which led to Euler's discovery of the column formula; but this did not happen until a clever experimentalist found that column strength varied directly as the area and inversely as the square of the length. In

[33] Leonard Euler: "Methodus inveniendi Lineas Curvas maximi minimique proprietate gaudentes, sive Solutio problematis isoperimetrici lastissimo sensu accepti." Lausannae & Genevae, MDCCXLIV; Additamentum I, "De Curvis elasticis," pp. 245 to 311.

1744[33] Euler first developed his now famous column formula; in 1757[34] he developed the formula in a more general form and discussed it in great detail. Then came Thomas Young (1773–1829)[35] with his very practical conception of E. In 1855, it remained for Bessemer first to produce an economical and strong metal building material. As time has passed, many column formulas have been proposed by such men as Euler, LaGrange, Schneider, Rankine, Johnson, Engesser, etc., and special formulas by such men as Gordon, Ritter, Swain, Merriman, Considére, von Kármán, Westergaard, E. H. Salman, O. H. Basquin, Hickerson, D. H. Young, etc.

None of these men has said much more than Euler and LaGrange; and they have omitted and warped much of the original. The formula proposed in the paper is in direct contradiction with those derived by J. Prescott, for example.[36] Too much attention has been paid to producing new formulas and not enough to securing more accurate data and applying them. More tests on really high-strength rolled columns of solid cross-section or rolled structural shape are needed. This would be valuable rational data for a rational column formula.

The Engineers of the U. S. Army Air Corps have derived twelve formulas, illustrated by graphs, which are more accurate and useful than any of the other column formulas (except that by Euler).[37] These formulas involve the use of E as a constant although some steels have a proportional limit of 51 000 lb per sq in. and a yield point of 174 000 lb per sq in.[38] The author also assumes E to be constant although in Fig. 1 it is quite apparent that it may vary considerably from $f = 0$ to $f = f_y$, because then E becomes the secant modulus, and, in many tests, E has been shown to decrease from 60 to 70%, although the material is able to keep a constant load. In tests conducted at the Structural Laboratory of Northwestern University School of Engineering, the writer found that columns reach their maximum strength after they have deflected laterally. This fact was noted in tests recorded many years ago by the late George F. Swain, Past-President and Hon. M. Am. Soc. C. E.,[39] and also in the formula developed by Euler,[33] namely,

$$P = \frac{\pi^2 E I \sqrt{1 + \theta^2}}{L^2} \qquad (82)$$

Mr. Young feels that he should accept such standards as happen to exist. The type that happens to be fabricated most generally is taken as a standard; but what about the sub-average column? To the writer it seems that the standard should be a minimum fixed by engineers rather than by fabricators. He has seen structural sections 10 ft long made as accurate in cross-section as any commercially machined material with an error (or δ) of -0.01 in., or

$\frac{\Delta}{L} = \frac{0.01}{120} = \frac{1}{12\,000}$. This is thirty times as accurate as the author's standard. In ordinary work the steel companies can produce an accuracy of $\frac{1}{9\,220}$. From 1874 to 1898 strength of steel produced for the major bridges decreased 40% and from 1898 to 1924 it decreased (with rare exceptions in both cases) 6½ per cent.[40] Nevertheless, for the more important bridges, engineers are consistently thinking of stronger steels, which leads to more and better bridges. Unless useful study of columns is advanced so as to create less expensive bridges (which means also using material of higher specific strength as in airplanes), not many more bridges will be built—although, of necessity, a few will have to be built from time to time. Let the engineer step forward and declare what should, will, and is to be, rather than what may happen to be, taken as the standard.

Little has been concluded, definitely, concerning the strength of steel columns. Every city has its own formula; every State has one, and every group of engineers. Separate column formulas are offered for bridges, buildings, ships, airplanes, and airships. Mr. Young mentions the general fact that there are too many column formulas, but does not demonstrate how he applies his formula to the various types of columns just mentioned. They should be expressed by one formula because they are all fundamentally the same. Investigators, however, always seem to favor some new mathematical expression. In 1757 Euler favored a great number of tests on the subject in question. If one were to translate Euler's work and LaGrange's work completely and undertake a series of useful, complete, but inexpensive column tests on the basis of their findings, one would at least have a rational idea of the problem. In studying built-up columns at present, the profession seems to be complicating the column subject rather than leading the way to a stiffer and stronger column.

Although the author touches on many important points of the subject in question, it is not clear how he will apply his formula to a member of great strength, and as a guide or aid in research. His formula does not follow that of Euler in the range that Euler's has been proved valid, or for columns that are straight. The work of the Society's Special Committee on Steel Column Research[41] presents many points of importance not explained by Mr. Young's paper. The unit stresses used to-day in column design represent about 6% of the unit stresses developed in columns that have been tested. The design of rigid frames is not a complex problem of designing columns, but a combination of the analysis of column and beam action. Elasticity, crookedness, eccentricity, and end conditions of columns have been, and can be, controlled. This paper reveals the results of considerable thought and labor and this discussion is intended only to emphasize the fact that the data upon which it is based are inadequate, when E, an assumed constant, may vary from 60 to 70 per cent.

R. G. STURM,[42] ASSOC. M. AM. SOC. C. E., AND MARSHALL HOLT,[43] JUN. AM. SOC. C. E. (by letter).—Some of the fundamental principles of instability are applied, in this paper, to the design of steel columns, assuming that when the maximum stresses reach the yield strength the column becomes unstable.

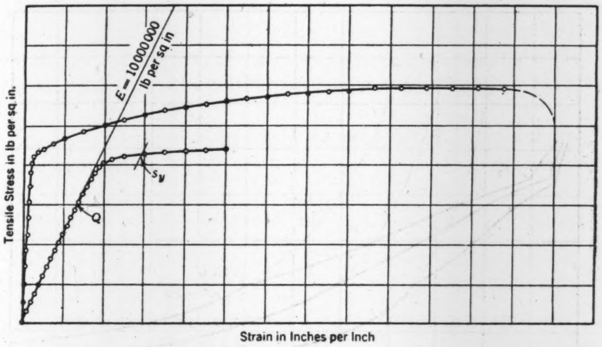

FIG. 23.—TYPICAL STRESS-STRAIN CURVES FOR A NON-FERROUS METAL.

The stress-strain curves of most non-ferrous metals differ from those shown in Fig. 1 by virtue of the fact that they depart gradually from the extended initial modulus line. A typical stress-strain curve for aluminum alloys, for example, is shown in Fig. 23. In applying these principles of instability, this stress-strain curve was idealized as one in which the value of the tangent modulus decreases as a straight line from the initial value at the upper limit of the elastic range to a value, λE, at the yield strength (0.2%), and from this decreased value along another straight line to zero at the modulus of failure. (The elastic range of the material may be determined by any standard method because reasonable variations in the actual value will not materially change the computed column strength.) Following the principles proposed by Engesser,[44] the critical load on a perfectly straight column was taken as the value given by Euler's formula, using the value of the reduced tangent modulus corresponding to the average stress in the column at buckling. A relation between the critical stress and the slenderness ratio thus obtained is shown in Fig. 24.

In the case of imperfect or eccentrically loaded columns in which the member deflects appreciably, the principles used by the author are the same as those established by T. Claxton Fidler[45] in 1887, namely, that the imperfections and eccentricities in the column can be represented by a sine curve. This leads to Fidler's formula for deflection which is the same as the author's Equation (8). This analysis was advanced still further by Ayrton and Perry[46] and formulas for the stresses in imperfect columns were developed. The formula for maximum stress at the center of an imperfect column is identical with the author's Equation (11).

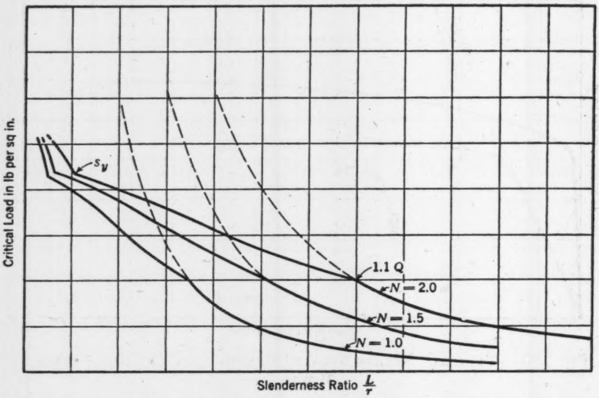

FIG. 24.—RELATION BETWEEN SLENDERNESS RATIO AND BUCKLING LOADS OF STRAIGHT COLUMNS (MADE FROM NON-FERROUS METALS).

If the initial eccentricities in the column are small, such that the maximum average stress developed in the column exceeds the elastic range of the material, the writers found, in their analysis for columns of aluminum alloys, that the value of s_e may be reduced according to the foregoing idealized stress-strain curve. The relations between the reduced value of s_e (say, s'_e) and the average stress in the column, s, are given by the following equations: When f_m exceeds 1.1 times the upper limit of the elastic range of the material, Q, but when s is still less than 1.1 Q, the value of s'_e becomes,

$$s'_e = s_e \left[1 - \frac{1}{j}\left(\frac{f_m - Q}{f_u - s}\right)^2\right] \ldots\ldots\ldots\ldots\ldots\ldots (83)$$

in which j is a factor depending upon the form of the member such that: $j = 4$ for solid rectangular sections; $j = 3$ for tubular sections; and $j = 2$ for I and H-sections bending parallel to the web (for bending perpendicular to the web the same as rectangles).

When s is between 1.1 Q and s_y,

$$s'_e = s_e \left[1 - (1 - \lambda)\,\frac{s - Q}{s_y - Q}\right] \ldots\ldots\ldots\ldots\ldots\ldots (84)$$

---

[46] "On Struts," by Professors W. E. Ayrton, and John Perry, *The Engineer*, December 10 and 24, 1886.

in which, s_y = the stress at 0.2% permanent set; and λ is a factor that ranges from 0.05 to 0.12 depending on the particular alloy.

When s is greater than s_y,

$$s'_e = \lambda\, s_e \left[1 - \frac{s - s_y}{f_u - s_y}\right] \ldots\ldots\ldots\ldots\ldots\ldots (85)$$

In this way it is possible to extend Equation (11) into the plastic range for aluminum alloys. The maximum fiber stress, f_m, can thus be computed for the plastic range by a simultaneous solution of Equation (11) and Equations (83), (84), and (85).

Fixity of the ends of columns may be considered by re-defining s_e in the more general expression,

$$s_e = \frac{N^2\, \pi^2\, E}{\left(\frac{L}{r}\right)^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (86)$$

in which, N is the Eulerian constant for end restraint (that is, $N = 1$ for hinged ends; and $N = 2$ for fixed ends).

It was found that columns fail by bending when the value of f_m reaches the modulus of failure for the material which for non-ferrous metals is practically equal to the tensile strength of the material, except for cases of local buckling.

The writers have used the equivalent of the author's Equation (12) to determine the ultimate load-carrying capacity of a column of aluminum alloys with the following changes: (*a*) s_y is replaced by s_u, the ultimate carrying capacity of the member; (*b*) f_y is replaced by f_u, the tensile strength of the material; and (*c*), s_e is replaced by s'_e. Thus, the ultimate strength of columns made of materials not exhibiting the definite yield point of mild steel may be computed by the following equation, similar to Equation (12):

$$s_u = \frac{f_u}{1 + \frac{\Delta}{k}\left(\frac{1}{1 - \frac{s_u}{s'_e}}\right)} \ldots\ldots\ldots\ldots\ldots\ldots (87)$$

It must be understood that Equation (87) applies only to columns that fail as a unit and not to those that fail by local buckling or twisting. In some cases, local buckling can be taken care of by a proper choice of the value of f_u.

These principles and equations can be applied to columns subjected to a combination of axial and transverse loads by treating the transverse load (or moment) as being applied first and considering the deflection produced by this load as an eccentricity of application of the axial load. The amount of stress that can be developed by the action of the axial load (residual stress, f_r), is equal to the modulus of failure, f_u, minus the bending stress, f_b, produced by the transverse loads. A satisfactory agreement was found between the strengths of heat-treated steel and duralumin tubes under combined axial and transverse loads computed in the foregoing manner and obtained from actual test results.[47]

For the aforementioned case of combined axial and transverse loading, Equation (87) becomes,

$$s_u = \frac{f_u - f_b}{1 + \frac{\Delta b}{k}\left(\frac{1}{1 - \frac{s_u}{s'_e}}\right)} \quad \text{.....................(88)}$$

in which, f_b = the stress resulting from the transverse bending; and Δb = the deflection resulting from transverse bending, assuming the initial crookedness to be negligible compared to the deflection.

The equivalent of the author's Equation (13) becomes,

$$s_w = \frac{f_u - f_b}{n + \frac{n\,\Delta b}{k}\left(\frac{1}{1 - \frac{n\,s_w}{s'_e}}\right)} \quad \text{...............(89)}$$

The deflection resulting from the transverse loads, Δb, may be closely approximated by,

$$\Delta b = \frac{f_b\,L^2}{\pi^2\,E'\,c} \quad \text{.........................(90)}$$

in which, E' = a reduced value of E such that,

$$\frac{\pi^2\,E'}{\left(\frac{L}{r}\right)^2} = s'_e \quad \text{.........................(91)}$$

Substituting Equation (91) into Equation (89) and replacing k by its equivalent, $\frac{r^2}{c}$, Equation (89) becomes,

$$s_w = \frac{f_u - f_b}{n + \frac{n\,f_b}{s'_e}\left(\frac{1}{1 - \frac{n\,s_w}{s'_e}}\right)} \quad \text{...............(92)}$$

The writers did not use the secant formula to determine the equivalent of the author's Equations (14), (15), and (16), because the expression became quite involved when a reduced effective modulus was necessary.

---

[47] "Strength of Tubing Under Combined Axial and Transverse Loading," by L. B. Tuckerman, S. N. Petrenko, and C. D. Johnson, Technical Notes of National Advisory Com. for Aeronautics, No. 307, June, 1929.

Under the heading, "Columns in Rigid Frame Construction," the author refers to the elastic action of other members meeting at a joint causing columns to act intermediately between pin-ended and completely fixed-ended conditions. Although he might have intended pin-ended conditions to cover the case of columns with end moments, it should be stated that the other members framing into a joint might throw sufficient initial bending into the column so that the ultimate strength in the assembly might be less than that of a pin-ended column axially loaded (without end moments). An extension of Manderla's original work[48] taking into account the axial stresses in computing secondaries in a truss, leads to the conclusion that continuity in a compression member offers no restraint in itself to end rotation as the load on the member approaches the buckling load. It would be of value if Mr. Young would explain his conception of the end fixation of columns.

F. E. TURNEAURE,[49] M. AM. SOC. C. E. (by letter).—The analysis of columns presented by Mr. Young is a valuable contribution. In some respects it differs somewhat from that presented by the Special Committee of the Society on Steel Column Research,[50] while in other ways it is in agreement. In view of the importance of the subject and the comprehensive nature of these two studies, it will be useful to compare them briefly.

Mr. Young is in agreement with the Committee's conclusions in regard to using the yield-point strength as the critical stress to be considered, and that elastic conditions may be assumed for stresses below this point. The variation in yield point and in the form of the stress-strain curve in the vicinity of this point, both below and above, renders a more exact treatment of buckling strength of little practical value for structural columns.

As the basis of his fundamental formula Mr. Young has adopted a centrally loaded, curved column and has superimposed upon this column any eccentricity that may occur. From the first, the Special Committee on Steel Column Research used the so-called secant formula, based entirely on eccentricity, and included in the eccentricity the effect of crookedness. The Committee selected this method in order to simplify the analysis of its test results where a definite eccentricity was used, and the final analysis leading to working formulas was made by including the effect of crookedness in the assumed eccentricity. The results of these two methods of procedure are not materially different. Analyses of crookedness made by the Committee and reported in its second progress report[51] indicate a much lower value for crookedness coefficient than Mr. Young has used. From its studies the Committee adopted a crookedness value, in terms of eccentric ratio, of $\frac{ec}{r^2} = 0.001 \frac{L}{r}$. This compares with a value of about $0.003 \frac{L}{r}$, which Mr. Young generally utilizes $\left(\Delta = \frac{L}{400}\right)$. This is a relatively high value and much larger than appears to be justified by the studies of the Committee.

[51] *Loc. cit.*, Vol. 95 (1931), p. 1152.

A column in a modern riveted truss is substantially a member of a rigid frame and, therefore, is subject to the secondary stresses, or end deformation moments, that occur in such frames. Mr. Young suggests that these secondary stresses be calculated and the column formula modified accordingly for each member. In its study of working formulas the Committee carefully considered this matter and suggested that for ordinary design purposes it would be reasonable to assume an eccentric ratio, $\frac{ec}{r^2} = 0.25$, for all columns and to assume a free length (between points of inflection) of 75% of the full column length in applying the theoretical formula. A column in a rigid frame having 25% secondary stress at each end, and in such a direction as to bend the member in single curvature, acts nearly like an eccentrically loaded, pivoted-end column of one-half the length and with an eccentric ratio of 0.25.

The Committee felt justified, therefore, in using a column length of three-fourths the full length for a practical working formula. The application of these ideas resulted in a secant formula representing the ultimate strength of the column, based on yield-point strength. Any desired factor of safety could then be applied to this ultimate strength formula. The working formula that was suggested was a parabolic curve coinciding substantially with the resulting secant curve within the usual working limits of $\frac{L}{r} = 40$ to 150. This working formula, adopted recently by the American Railway Engineering Association, is:

$$s = 15\,000 - \frac{1}{4}\left(\frac{L}{r}\right)^2 \dots\dots\dots\dots\dots\dots (93)$$

Pin-ended columns are not frictionless, but the amount of secondary moment at the ends due to truss deformation is limited. If frictionless, the eccentricity of load would be limited by the effect of crookedness and other incidental column defects; if frictional resistance is sufficiently large, such columns act as riveted members. As a reasonable estimate, the Committee adopted the same eccentric ratio of 0.25 as for riveted columns, but increased the free length to 85% of the full length, leading to the parabolic working formula,

$$s = 15\,000 - \frac{1}{3}\left(\frac{L}{r}\right)^2 \dots\dots\dots\dots\dots\dots (94)$$

For large and important structures, the writer endorses, fully, Mr. Young's suggestion that secondary stresses be computed and the column formula modified accordingly. The Committee's formula provides for eccentricity acting in the same direction at both ends. However, most columns in a truss will be bent in reverse curvature, resulting in maximum stresses at the ends; and such columns might well be designed at a fixed basic unit strength without reduction for column length. For ordinary practice as covered by general specifications, one would scarcely resort to such a separate calculation, and a single formula is preferable.

The shear analysis presented by Mr. Young appears to be quite complete, and shows clearly the high stresses possible in short members, decreasing to a smaller value with increasing length and then increasing again for long members. In this case, again, the high values assumed for crookedness result in shear values differing somewhat from those corresponding to the column formulas of the Committee. The new shear formula recently adopted by the American Railway Engineering Association was based upon the analyses by Shortridge Hardesty, M. Am. Soc. C. E., using the adopted secant formulas as a basis. This new formula is an empirical one, but is constructed so as to provide reasonably well for both short and long columns, as follows:

$$\frac{V}{P} = \frac{1}{100}\left(\frac{100}{\frac{L}{r} + 10} + \frac{\frac{L}{r}}{100}\right) \dots\dots\dots\dots\dots (95)$$

in which, $\frac{V}{P}$ = ratio of shear to direct stress.

It appears to the writer that the paper by Mr. Young and the reports of the Special Committee on Steel Column Research, taken together, present a clear picture of the underlying factors in the rather complex column problem, and suggest rational methods of dealing with the subject.

N. J. DURANT,[52] ASSOC. M. AM. SOC. C. E. (by letter).—Simple rational formulas for the design of steel columns, which are deduced from elementary analyses, are brought to the attention of the Engineering Profession by this paper. The subject of column analysis is one of the oldest in the broad field of elasticity, but in spite of all the research conducted, the profession has used empirical formulas for years, with the result that, to-day, the engineer has a multiplicity of column formulas at his command, no two of which will give identical results.

These formulas (whether straight lines, parabolas, or of the Rankine-Gordon type), which have been in general use, are merely forms of wasted ingenuity. Usually, the only parameter in them is the slenderness ratio, $\left(\frac{L}{r}\right)$. One of the disadvantages of such formulas (whether or not they conform to test results of a particular material) is, that immediately the designer is confronted with a material with which he is unfamiliar, he feels the necessity for an analysis which will interpret for him the principles as distinct from the incidents upon which experimental results depend.

The chief disadvantage of the approximate formulas, however, lies in the fact that unless the engineer has a rational formula to serve as a standard, he is in complete ignorance regarding their factors of safety, and this alone should be a sufficient reason for their condemnation.

---

[52] Senior Engr., Rendel, Palmer & Tritton, Westminster, London, England.

It follows that the engineer must be in doubt regarding the stability of the resulting structures, because it is no criterion that such structures withstand the loads for which they have been designed.

Objections to rational column formulas have been raised because they have been considered too complicated for general use. No formula for columns could be so complicated but that a graph or tabular values of the dependent variable for different values of the argument could not be readily obtained, and this is all the average designer needs. His subsequent uses of the formula, therefore, would involve no additional work beyond that entailed by the use of an approximate formula.

Furthermore, in the case of an investigation, whether of failure of a column or for other reasons, the investigator would arrive at precisely the same formulas as did Mr. Young for similarly imposed conditions.

A rational formula for columns cannot be condemned because it is complicated; neither can a straight-line formula be defended on the basis of its simplicity. Simplicity is a desideratum to be aimed at in any formula, whatever its purpose, but if all the essential variants are absent, the formula ceases to be of general value.

A formula for the design of columns should be one of general utility and if it has a theoretical basis, then by a variation of the fundamental elastic constants it would apply to any material which obeys Hooke's law and which has a compressive or tensile stress-strain curve. Moreover, if the factor of safety in the column formula is equal to that of the material in tension, the resulting structure will have, within narrow limits, a uniform strength.

The only actual uncertainty in a rational column formula is the value which should be assigned to the length of the column. If the ends were fixed in position and direction this value would be determinate, but such a condition is unattainable.

All members of a frame are subjected to varying degrees of constraint which make the effective length indeterminate, but the true effective length, of course, must be less than the geometric length. If the geometric length were inserted in the formula, the designed column would have a strength greater than that calculated, provided, of course, the material was in no way impaired and that the secondary moments were properly assessed. The value of the constraints will be less, in general, for increases in the yield stress, but no analytical law can be formulated to deal with this phenomenon.

Moreover, the more slender a member is compared with those to which it is attached, the shorter will be its effective length. This statement, although obvious, serves in some measure to fix the effective length of a column. For instance, the web members of a truss are almost invariably of more slender proportions than the chords and, in consequence, their effective lengths are less than their geometric lengths. In general, the chords receive little restraint from the web members and probably their effective lengths are their geometric lengths, approximately.

Throughout his paper the author has used the equation,

$$E\,I\,\frac{d^2y}{dx^2} = -\,M \ldots\ldots\ldots\ldots\ldots\ldots\ldots (96)$$

which is sufficiently accurate for columns of solid cross-section.

For built-up columns, the form is of importance and it would be necessary in a rigorous investigation to use the more general equation:

$$E\,I\,\frac{d^2y}{dx^2} = -\,M + k\,\frac{E\,I}{A\,G}\,\frac{d^2M}{dx^2} \ldots\ldots\ldots\ldots\ldots (97)$$

in which k is a constant depending on the distribution and form of the area of the cross-section, and G is the modulus of rigidity.

However, considering the variation in the elastic constants and the diversity of column forms, Equation (97) would not be expedient for general use.

To avoid the anomalies in design created by the approximate formulas, it is to be hoped that a rational formula for column design will soon be incorporated in all specifications for the design of structures.

So much research work has been done on structures, particularly in America, that it appears strange that the march of progress should be marred by adherence to traditional standards, many of which, have no scientific significance.

E. C. Hartmann,[53] Assoc. M. Am. Soc. C. E. (by letter).—The various factors involved in the rational design of steel columns have been treated in a comprehensive manner by the author, but the writer is inclined to wonder how much of the paper is likely to be absorbed in usable form by those actively engaged in column design. What most designers want is something reasonably accurate and not too complex, which will take into account the principal variables and will fit neatly into the ordinary design specifications. In the case of a column subjected to eccentric load, or to a side load, for example, the designer would like to know what allowable stress to use on the extreme fiber. Knowing this, he is perfectly competent to proceed with his design in the usual manner, selecting a member on which the combined stress (bending plus direct stress) does not exceed the allowable.

A simple formula for determining the allowable stress for all types of compression members, which incorporates practically all the principles in the author's paper, has been derived by the writer and his associates. For the sake of simplicity the derivation presented herein will be made for steel columns using the same basic assumption as that adopted by the author, namely, that the yield-point stress is the limit of usefulness. It will then be shown how the derivation may be extended to include materials such as the structural alloys of aluminum which have no pronounced yield point and, hence, have a range of useful stress above this point.

---

[53] Research Engr., Aluminum Co. of America, New Kensington, Pa.

Fig. 25 demonstrates a very general case of a pin-ended column having an initial crookedness, Δ, loaded eccentrically at a distance, e, and resisting a side load as well as the column load. The dotted line represents the deflected position of the member under load.

Let the column load, P, and the side load, W, be the design loads for which a factor of safety, n, is to be provided. If the column is properly designed, the fiber stress from combined bending and direct stress should just reach the yield point if P is increased to $n\,P$, and W to $n\,W$, simultaneously. Therefore, the following equation represents the condition at failure:

$$\frac{n\,P}{A} + \frac{n\,P\,e\,c}{I} + \frac{n\,P\,\Delta\,c}{I} + \frac{n\,P\,D\,c}{I} + \frac{n\,M\,c}{I} = f_y . \tag{98}$$

in which, in addition to the notation of the paper, D = the total deflection which accompanies the yield-point stress, caused by all loads combined, in inches; and M = the maximum bending moment produced by transverse loads, in pounds. It will be recognized that Equation (98) is simply a summation of the five component parts of the extreme fiber stress, based on the well-known fundamental equation for combined stress:

$$f = \frac{P}{A} + \frac{M\,c}{I}.$$

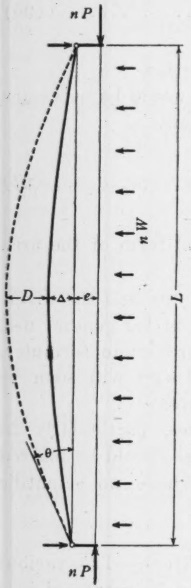

FIG. 25.

Transposing the fourth term in Equation (98) to the right-hand side and dividing through by the factor of safety, n:

$$\frac{P}{A} + \frac{P\,e\,c}{I} + \frac{P\,\Delta\,c}{I} + \frac{M\,c}{I} = \frac{f_y}{n} - \frac{P\,D\,c}{I} \;\ldots\ldots\ldots\ldots \tag{99}$$

The term, $\frac{f_y}{n}$, in Equation (99), may be replaced by f_b, the design stress for the member treated as a beam, which gives:

$$\frac{P}{A} + \frac{P\,e\,c}{I} + \frac{P\,\Delta\,c}{I} + \frac{M\,c}{I} = f_b - \frac{P\,D\,c}{I} \;\ldots\ldots\ldots\ldots \tag{100}$$

Since P and W are design loads (ultimate loads divided by the factor of safety, n), and since M is the moment produced by the design load, W, the terms on the left-hand side of Equation (100) represent the ordinary design calculations for combined stress on the extreme fiber of the member. The equation states that if this calculated stress is equal to the terms on the right, a factor of safety of n is provided against failure (yield-point stress). Therefore, the terms on the right constitute the allowable design stress, f_w; thus:

$$f_w = f_b - \frac{P\,D\,c}{I} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \tag{101}$$

in which f_w = the allowable combined stress, in pounds per square inch, on the extreme fiber at the center of the unsupported length of any member subjected to combined bending and direct stress (includes eccentrically loaded columns); and f_b = the allowable stress, in pounds per square inch, for the member treated as a beam.

The only term in Equation (101) that is unknown is D, the total deflection accompanying the yield-point stress. This deflection may be expressed as the sum of the effects of the various loads, but a simpler and more direct solution is to express it directly in terms of the known total fiber stress, as follows:

$$D = \frac{\left(f_y - \frac{n\,P}{A}\right) L^2}{\pi^2\,E\,c} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (102)$$

Equation (102) is readily derived by the use of the well-known moment-area theorem which states that the deflection at the center of a span is the bending moment at the center produced by the moment diagram, divided by EI, considered as a load.

The total bending stress at the center is $f_y - \frac{n\,P}{A}$ and, if M' is the total moment causing this stress:

$$\frac{M'\,c}{I} = \left(f_y - \frac{n\,P}{A}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (103)$$

Therefore, in this case, the center ordinate of the moment diagram, divided by $E\,I$, is:

$$\frac{M'}{E\,I} = \frac{\left(f_y - \frac{n\,P}{A}\right)}{E\,c} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (104)$$

The constant, π^2, in Equation (102) results from assuming that the curve of moments is a sine curve and in this respect Equation (102) is an approximation. Other curves might be assumed; for example, a parabolic moment curve gives a constant, 9.6, instead of π^2.

Let s_e = the critical stress, in pounds per square inch, for the member treated as an Euler column, representing the Euler value, $\frac{\pi^2\,E\,r^2}{L^2}$, as in the author's paper. Transposing terms:

$$\frac{L^2}{\pi^2\,E} = \frac{r^2}{s_e} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (105)$$

Substituting Equation (105) in Equation (102) gives the following:

$$D = \frac{\left(f_y - \frac{n\,P}{A}\right)}{s_e}\,\frac{r^2}{c} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (106)$$

The term, f_y, may be replaced by $n\, f_b$, which gives:

$$D = \frac{\left(f_b - \frac{P}{A}\right)}{\frac{1}{n}\, s_e}\, \frac{r^2}{c} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (107)$$

Substituting Equation (107) in Equation (101) and replacing I by $A\, r^2$:

$$f_w = f_b - \frac{P}{A}\, \frac{\left(f_b - \frac{P}{A}\right)}{\frac{1}{n}\, s_e} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (108)$$

The derivation of Equation (108) for end conditions other than pinned is relatively simple and leads to the same formula. The method preferred by the writer is to evaluate the end condition in terms of the equivalent length of pin-end column—that is, in terms of the length between the points of contraflexure of the member. Thus, a fixed-end column acts the same as a pin-end column of one-half its length. Since the line of action of the column load, P, must follow the straight line joining the points of contraflexure, the derivation is simply a repetition of the foregoing, except that the effective length, $z\, L$, is substituted for L and the effective initial crookedness, $z\, \Delta$, is substituted for Δ. The Euler value, s_e, becomes $\frac{\pi^2 E\, r^2}{(z\, L)^2}$. The value of z for completely fixed ends is 0.5. For round or pin ends, it is 1.0, of course, whereas for the general run of framed ends many designers use 0.75 as a representative average value.

As previously pointed out, the derivation of Equation (108) is based on the line of reasoning adopted by the author in dealing with steel. For aluminum alloys and other materials which do not display the abrupt yield-point characteristic of steel, it is necessary to introduce into the derivation a suitably reduced modulus of elasticity, E_a, when the value of $\frac{n\, P}{A}$ exceeds the elastic range. A similar correction should be made even in the case of steel, because the limit of the elastic range is slightly below the yield-point stress. This matter is not as important in steel as in most other materials.

If applied to a column that is eccentrically loaded, the method described herein gives the same result as that in the author's paper. Furthermore, it has the additional advantage that it applies to columns transversely loaded; in fact, it allows any member under combined bending and direct compression to be designed on the same basis as an ordinary beam, with no departure from conventional procedure. In order to clarify the method of using Equation (108) a simple example may be cited, using current standard specifications[54] as a basis for design. Let the problem be to determine whether a 12-in., 65-lb Carnegie beam section, unbraced, on a 15-ft simple span (pin ends) is safe under the combined action of an end load of 200 000 lb and a distributed transverse load of 20 000 lb, acting in the plane of the web. The following are the calculations:

---

[54] Specifications for Steel Railway Bridges (1934), Am. Ry. Eng. Assoc.

(1) $\frac{P}{A} = \frac{200\,000}{19.11} = 10\,500$ lb per sq in.; $\frac{L}{r}$ (Axis 2–2) $= \frac{15 \times 12}{3.02} = 59.6$; and, the allowable axial compression $= 15\,000 - \frac{1}{3}\,\overline{59.6^2} = 13\,800$ lb per sq in. Consequently, the member is safe for the column load alone.

(2) The bending stress (Axis 1–1) $= \frac{20\,000 \times 15 \times 12}{8 \times 88} = 5\,100$ lb per sq in.; $\frac{L}{b} = \frac{15 \times 12}{12} = 15$; and $f_b = 18\,000 - 5 \times \overline{15^2} = 16\,900$ lb per sq in. Therefore, the member is safe for transverse load alone.

(3) The combined fiber stress (Axis 1–1) $= 10\,500 + 5\,100 = 15\,600$ lb per sq in.; $\frac{L}{r}$ (Axis 1–1) $= \frac{15 \times 12}{5.28} = 34$; s_e (Axis 1–1) $= \frac{\pi^2 E}{34^2} = 248\,000$ lb per sq in.; $n = \frac{33\,000}{18\,000} = 1.83$; $\frac{1}{n}\, s_e = 135\,000$ lb per sq in.; and f_w (Axis 1-1) $= 16\,900 - 10\,500\, \frac{(16\,900 - 10\,500)}{135\,000} = 16\,400$ lb per sq in., which proves the member safe for combined load.

In the foregoing examples it should be noted that, for checking the strength of the member under column load alone, the smallest radius of gyration is used (Axis 2–2), whereas for checking combined stress conditions the radius of gyration is taken about the axis normal to the plane of the transverse bending loads (Axis 1–1).

In using Equation (108) the end conditions for the transverse loading should be consistent with those for the column loading. Thus, in the foregoing example, if the member were assumed to have riveted ends, the value of s_e would have been computed for $z = 0.75$,[55] and, therefore, in computing the bending stress from the transverse load the effective span should be reduced to 0.75 × 15.

Certain parts of the foregoing derivation can be used in arriving at a formula for estimating the maximum shear on compression members. Assuming the deflected member in Fig. 25 to take the form of a sine curve, it can readily be shown that the maximum slope of the member is:

$$\tan \theta = \frac{\pi\,(D + \Delta)}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (109)$$

The total shear on the member is:

$$n\,V = n\,B + n\,P \sin \theta \quad \ldots\ldots\ldots\ldots\ldots\ldots (110)$$

in which B is the shear force, in pounds, produced by the transverse load, W. Neglecting the difference between tan θ and sin θ and dividing through by the factor of safety, n, gives the following equation:

$$V = B + \frac{\pi\,P\,(D + \Delta)}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots (111)$$

---

[55] Specifications for Steel Railway Bridges (1934), Am. Ry. Eng. Assoc., Appendix A.

in which V = the total shear force, in pounds, for which the column should be designed (shear at failure divided by factor of safety). Substituting the value of D from Equation (107),

$$V = B + \frac{\pi\ P}{L}\left[\frac{\left(f_b - \dfrac{P}{A}\right)}{\dfrac{1}{n}\ s_e}\ \frac{r^2}{c} + \Delta\right] \text{..........} (112)$$

Equation (112) is for pin-ended members only ($z = 1$). It may be generalized as to end conditions by using $z\ L$ instead of L, and $z\ \Delta$ instead of Δ, in accordance with the foregoing discussion of end conditions; thus:

$$V = B + \frac{\pi\ P}{z\ L}\left[\frac{\left(f_b - \dfrac{P}{A}\right)}{\dfrac{1}{n}\ s_e}\ \frac{r^2}{c} + z\ \Delta\right] \text{..........} (113)$$

in which V = the maximum total shear force, in pounds, for which compression members must be designed in order to provide a factor of safety against shear failure consistent with that against column failure. The Euler value, s_e, should be calculated for the effective length, $z\ L$. The shear, B, from transverse loads should also be that for the effective length, $z\ L$.

Equation (113) fits in nicely with Equation (108) since the two have a number of terms in common. It should be emphasized that the radius of gyration, r, should be taken about the axis normal to the plane in which the shearing force, V, is acting. The distance to the extreme fiber, c, should be taken in a direction consistent with r and, in the case of unsymmetrical members having two values of c, the smaller of the two should be taken unless transverse loads or eccentricities are present which throw the larger compression stresses on the other side.

Equation (113) like Equation (108) gives results in agreement with the author's method when applied to a column eccentrically loaded; and has the additional feature that it applies also to columns transversely loaded. In order to clarify the method of using Equation (113) an example may be given using the same set of conditions as in the foregoing example. The following are the calculations: $B = \dfrac{20\ 000}{2} = 10\ 000$ lb; $\dfrac{\pi}{L} = 0.0174$;

$$\frac{f_b - \dfrac{P}{A}}{\dfrac{1}{n}\ s_e} = \frac{16\ 900 - 10\ 500}{135\ 000} = 0.0474;\ \frac{r^2}{c} = \frac{5.28^2}{6.06} = 4.6;\ \Delta = 0;$$ and, V

$= 10\ 000 + 0.0174\ P\ [0.0474 \times 4.6 + 0] = 10\ 000 + 0.0038\ P = 10\ 760$ lb.

The shear produced by column action in this member is less than 1% of the end load, and is a small fraction of the total shear. If the initial crookedness had been assumed equal to $\dfrac{L}{400}$, or 0.45 in., the resulting shear from column action would be increased to 0.0116 P, and the total shear would be 12 300 lb. In either case, of course, the column selected has ample web section.

In his handling of the shear problem, the author has apparently overlooked the factor of safety. His v_y, which is defined as "the average shearing stress when the load, P, is at its yield-point value," is used in Fig. 16 for direct comparison with values taken from the American Railway Engineering Association specifications. He should have used v_w, or $\frac{v_y}{n}$, following the same logic by which s_w in his Equation (13) is arrived at from s_y in his Equation (12). This would have had the effect of dropping all his curves in Figs. 16 and 18 considerably. The writer wonders if the selection of an average design shear of 600 lb per sq in. would not have been affected by this correction. There is little in the paper to justify a blanket value of 600 lb per sq in. under any circumstances.

The author has pointed out the effect of shearing distortions on latticed or battened members. In the writer's derivations these distortions affect only the magnitude of the deflection, D. In Equations (102 and (107) it is assumed that shearing deformations are negligible. Actually, under the effect of transverse loads, the shearing deflection in a latticed member often runs as high as the bending deflection. Some account of this might be taken in Equations (108) and (113), possibly by inserting a suitable factor by which the term, $\left(f_b - \frac{P}{A}\right)$, is multiplied when latticed or battened columns are under consideration. This is a matter worthy of further study.

The writer would like to emphasize the importance of the term, D, the total deflection of the member, in the foregoing derivations. This deflection is that which occurs just at the point of failure, or just as the extreme fiber reaches the yield-point stress. Dividing through the various equations by the factor of safety, n, does not affect the magnitude of D, so that in the formula for working stress, f_w (Equation (101)), D is still the deflection corresponding to the yield-point stress. The significance of this to the designer is simply that, in estimating the degree of fixation of the ends of a member (magnitude of effective length, $z\ L$), the conformation of the member should be visualized with respect to conditions just before failure. Many a member which is practically fixed-ended ($z = 0.5$) at low loads may be practically pin-ended ($z = 1.0$) at or near failure, and should be so considered in design.

The writer advocates the use of Equations (108) and (113) in actual design instead of such generalities as $\Delta = \frac{L}{400}$ and average shear stress = 600 lb per sq in., advocated in the author's summary. The designer should be allowed some latitude to evaluate such variables as crookedness, end conditions, and eccentricity of loading in the light of his own peculiar design conditions. Most designers will quickly simplify the application of Equations (108) and (113) by preparing charts and other "short-cuts" for the routine problems, saving the formulas themselves for the unusual cases that always arise.

Edward Godfrey,[56] M. Am. Soc. C. E. (by letter).—The idea that a column is imperfect, that it is not perfectly straight, and that imperfection (lack of straightness) is directly proportional to the length of the column, is a rational assumption. Mr. Young's attack on the problem of the column is in the right direction. A perfect column formula, except for slender columns, is not possible, because a perfect column is an impossibility. The imperfection of a column that is easiest to detect, in columns otherwise carefully made, is lack of straightness. In 1909, the writer pointed out[57] that by visual inspection one can detect deviation from a straight line of about $\frac{1}{400}$ of the length of a structural member. This is the ratio suggested by Mr. Young. The writer chose $\frac{1}{300}$ as the ratio for a rational column formula to allow for eccentric end application of the load.

Mr. Young finds an expression for the total extreme fiber stress which includes the bending stress due to the bow of the column. His design curve for a rectangular section in that column, as shown in Figs. 9 and 10, is almost a straight line for values of $\frac{L}{r}$ up to 120 and for a bow in the column equal to $\frac{1}{400}$ of the length. It is evident that a somewhat larger assumed bow in the column would give a still closer approach to a straight line.

In the writer's solution, using an average value of the radius of gyration as one-third the depth of section, and an assumed bow in the column of $\frac{1}{300}$, the curve of allowed unit stress was found to be a straight line up to $\frac{L}{r}$ equal to about 110. This agreed with the commonly used straight-line formula, $16\,000 - 70\,\frac{L}{r}$. The deviation from this straight line is very slight for slenderness ratios of 150 or less. At $\frac{L}{r} = 150$ the curve strikes the Euler curve with a factor of safety of 2.

It is significant that this is just about the upper limit of structurally permissible columns. Thus, a completely rational formula, too cumbersome to use in practice, however, based on no other supposition than a bow or imperfection that would reject a column subject to ordinary inspection, agrees almost exactly with the common, well-tried, straight-line formula that never laid claim to any except experimental, empirical backing.

The writer recommended that columns be divided into two distinct classes (structurally permissible columns and slender columns), and that design stresses in these two classes be based on entirely different considerations, not forgetting, of course, the zone where the two classes overlap. The unit stress to be used in the first class was based solely on the extreme fiber stress in a bowed column, subject to an endwise load, and that unit stress was shown to be theoretically determinate by the use of a formula of the type, $16\,000 - 70\,\frac{L}{r}$. The unit stress in slender columns was recommended to be on the basis of a factor of safety, say, about 2, based on the ultimate load as shown by the Euler formula. There is no need of a factor of safety greater than 2 in slender columns, because the steel is in no manner distressed in a slender column (even in one having a decided bow) until the ultimate load is nearly reached.

[56] Structural Engr., Pittsburgh, Pa.

[57] *Railroad Age-Gazette*, July 2, 1909; see, also "Steel Designing," by Edward Godfrey; and *The Structural Engineer* (London), September, 1932.

There need be no confusion in the two classes of columns. Specifications for structures need give no recognition to slender columns, except to exclude their use. All structural columns can be designed safely on the same straight-line formula, because there is extra safety in the range approaching slender columns; this is of advantage, because the weight of members and other considerations make it desirable. Slender columns and formulas for them should be reserved for such work as transmission towers, airplanes, etc.

The writer is not familiar with present practice among Continental engineers, but in former years they used the Euler formula with a factor of safety of 5. This is an extravagant waste in slender columns, where the Euler load is of real significance. The Euler load has no meaning whatever in structurally permissible columns.

L. T. WYLY,[58] M. AM. SOC. C. E. (by letter).—The method of analyzing steel columns, proposed in this paper, is the most rational that has been advanced to date. The problem has been defined concisely by B. R. Leffler,[59] M. Am. Soc. C. E., as follows: "The problem of the column is one of bending moment. The very fact that a column fails with an average unit stress below the strength of the material is evidence that it is impossible to centralize the load at every section, * * *." The parabolic formulas now generally advocated and widely used omit entirely (except as covered by a constant, representing assumed average values) the important factors of eccentricity and the value, *c*. Any solution of a bending problem which neglects these terms can be neither logical nor complete. The writer feels, however, that before the Engineering Profession can adopt Mr. Young's procedure it must have a more general knowledge of secondary bending actions, and more definite information regarding actual eccentricities to be expected on columns, as determined by careful and comprehensive field and shop measurements. Furthermore, the rational design of steel columns must necessarily take into account a number of factors not represented in the formula but which directly affect the strength of the column. Among the latter are the following:

(1) The form of section including its strength under local buckling action;

---

[58] With Bureau of Bridges, Div. of Highways, Springfield, Ill.

[59] *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 541.

(2) Adequateness of design of connection, pin-plates, bracing, and other items unfortunately too often considered as secondary details; and,

(3) The relative degree of excellence to be expected in fabrication shops and in field construction in matters such as milling, setting shoes and grillages, and maintaining the structure in proper position during construction.

In short, it is the writer's conviction that a column formula should be tied up directly with specific clauses in design and construction specifications, and the formula used with a fairly accurate idea of how these specifications will be followed. The writer desires to discuss briefly some of the evidence supporting this view.

It should be recognized at the outset that the problem is concerned with short columns primarily, or, at most, with intermediate columns. The slenderness ratio, in the plane of the truss, of main columns of heavy bridges will usually be 40, or less, except in the inclined end posts where it may be 60 or 75. In a light highway bridge, particularly if rolled wide flange beams are used as columns, the ratio may be as high as 100. The $\frac{L}{r}$ ratio normal to the truss will usually be less. In short, the Euler values do not enter into the problem.

Computed Eccentricities.—If eccentricities in the plane of the truss are to be determined by secondary stress analysis, the following factors should be taken into account: (*a*) For a large bridge with subdivided panels and heavy chords the secondary hangers or struts will be relieved of considerable primary stress by the beam action of the chords, with consequent reduction of secondary moments on the chords themselves; and (*b*) with railway loadings the local effect of heavy drivers is likely to be severe on the secondary moments in the chords, and an accurate solution may be very tedious.

The foregoing facts have been established by J. I. Parcel and G. A. Maney,[60] Members, Am. Soc. C. E. There is the further question of whether, at the present time, it would be advisable to entrust the matter of a secondary analysis of a truss, and consequent selection of a column formula for individual members, to the average designer. The writer's view is that much more work will have to be done on this problem and certain standards established by the profession before the method will be satisfactory for adoption in a specification. The same applies to eccentricities arising in a plane normal to the truss due to floor-beam or other rigid-frame action.

Measured Eccentricities.—With regard to initial crookedness of columns, the Final Report of the Board of Engineers of the Delaware River Bridge, between Philadelphia, Pa., and Camden, N. J., shows measurements taken on twenty-two columns varying in length from 29 to 41 ft. Initial crookedness of ¼ in. and more was found, and was just as great in the short members as in the long. The writer has taken careful measurements on about sixteen columns fabricated for a large highway bridge by a modern shop and has found initial crookedness of ¼ to $\frac{5}{16}$ in. These columns were as long as 100 ft, and the sectional areas up to 75 sq in. and most of them had central longitudinal diaphragms included in the section. The short columns showed as much eccentricity as the longer ones. It is the writer's belief based on the foregoing information, and on discussions with shop foremen and inspectors, (1) that initial crookedness is not necessarily a function of length or $\frac{L}{r}$; (2) that it is likely to be as much as $\frac{1}{4}$ in. for a short column; and (3) that it should not exceed $\frac{3}{8}$ in., for a member 100 ft long if shop inspection is adequate. Furthermore, the writer would point out that it seems reasonable to believe that a column with a central longitudinal diaphragm or web-plate normal to the main webs should have less initial crookedness than one in which the webs are laced together, the shop work being easier in this respect. The writer would propose a clause in construction specifications limiting allowable initial crookedness of a column to an amount equal to 0.125 in. plus 0.0002 L (in which L is length of column, in inches), and making a greater amount than this cause for rejection.

---

[60] "Secondary Stresses in Kenova Bridge", *Bulletin No. 4*, Eng. Studies, Univ. of Minnesota, Minneapolis, Minn.

There are important initial end eccentricities to which columns may be subjected, which are not due primarily to rigid frame or secondary bending action but to what may be termed accidental misfits in shop or field work. Probably the most frequent are:

1.—Eccentricities due to improper column alignment due to such causes as the following: (*a*) Improper fit of lateral bracing may pull members out of line transversely; and (*b*) settlement of one or more falsework supports during riveting work.

2.—Eccentricities due to misfits at ends of columns which depend largely or wholly on direct bearing for transmission of load.

It should be noted that the methods of computing the ultimate strength of columns subjected to initial eccentricities of this type are not included by Mr. Young, since the eccentricity (that is, end moment divided by column load) is not constant, as may be assumed with eccentricities in a truss arising from secondary bending.

Any column may be subjected to eccentricities due to improper alignment, and unless careful check is maintained of the position of a structure during the construction stages such errors may easily escape detection. An example in the writer's experience is shown in Fig. 26 in which a bridge column, shop riveted to a length of 100 ft, was pulled out of line $\frac{3}{8}$ in. in the field by an improper fit of lateral bracing. This was corrected by reaming the lateral connections. Some idea of the shears that may occur in a column by this kind of accidental eccentricity is given by the curves shown in Fig. 27.

$\frac{3}{8}$ in
Truss Pulled out of Line by Lateral Bracing

FIG. 26.

It is the writer's belief that errors of this type occur more often than is generally realized.

Columns subject to eccentric loads due to imperfect end bearings include some of the largest and most important compression members in engineering structures. Among them are: (1) All end posts or main vertical posts at piers that bear directly on a footing, on pins, on shoes, or on grillages; (2) main truss, or building columns that depend partly or entirely on milled ends for load transfer at splices; (3) trunnion columns supporting main trunnion bearings or trunnion cross-girders in a bascule bridge, as well as columns supporting counterweights, or movable span and counterweights, in bascule or vertical lift bridges; and, (4) columns in movable bridges, that bear on main trunnions.

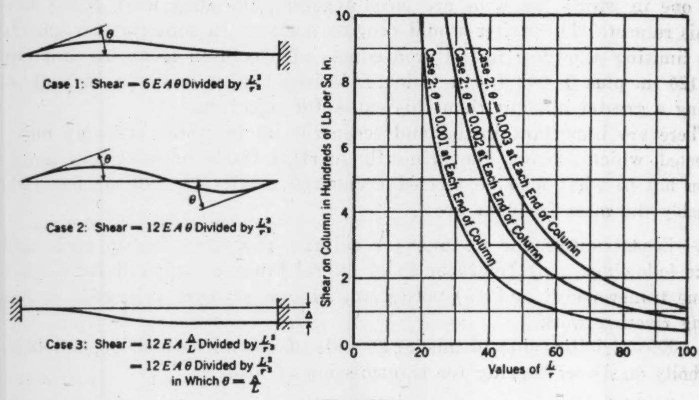

FIG. 27.

In through bridges most portal columns are in Class (1), and these may be subject to severe bending from lateral loads in addition to direct loads. A source of serious error in fit at tops of the columns of Class (3) may be the necessity for shimming between column top and base of bearing or of cross-girder. Frequently shims of varying thickness are used in this case. As it is manifestly impossible to get a thin shim which is perfectly flat, and as usually the weight of the bearings is not sufficient to iron out small waves in the shims, except in the case of the very largest bridges, it is evident that the bearing will not take its final position on the column until considerable dead load from the structure has been added, and at that time the actual error usually can not be detected or corrected. Where a cross-girder rests on the column the problem is further complicated by the fact that the girder will be subject to flexure—often much flexure—after the fit has been made and the dead load added to the girder. In the case of the columns of Fig. 28 special adjustments were made, after careful study, to take care of this matter. If there is any error in shop or field in making the center of the trunnion normal to the plane of rotation of the truss, the members of Class (4) and their connections are subject to racking or weaving.

In order to illustrate what may be expected from present practice in this matter there are shown, in Fig. 28 and Fig. 29, the results of careful measurements taken by the writer on the milled ends of trunnion columns on two different bascule bridges. In each case the grillage top plates were finished in the shop and were set in the field with great care. The measurements were taken after the columns had been lined in both directions and had been placed in proper position to receive the cross-girders or bearings supporting the movable leaf. Measurements of fit between grillages and columns were made by inserting thickness gauges between the top of the grillage plates and the base of the column, under the main material of the column. Measurements on the tops of the columns in Fig. 29 were taken in a similar manner. All measurements were checked independently by other observers. Attention is called to the fact that in Fig. 28 the actual milled surfaces vary from the normal by an angle of 0.0012 radian, and that in Fig. 29 the surfaces vary from the normal by as much as 0.003 radian. In each case the weight of the columns themselves is sufficient to cause them to come to a firm bearing at the bearing edge or corner. It is apparent in the case of these columns that the error in milling bears no relation to the slenderness ratio of the column. The columns in these two bridges were fabricated by two different firms, each enjoying well established reputations for high grade work, and the work was inspected by professional shop inspectors. Furthermore, it should be noted that in the case of each bridge, the milling of the columns of the second leaf (not shown), was very satisfactory. In the case of the columns shown in Fig. 29, a proper bearing of the member on the grillage was obtained by tilting the columns. The Final Report of the Special Committee on Steel Column Research[61] shows even greater errors in end milling.

[61] *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 1412.

Other instances of measured eccentricities at ends of columns due to errors in milling or in field work are, as follows:

(1) In the case of a large movable bridge carried on a heavy cross-girder which latter was seated through castings on heavy columns the writer found the load to be off center on one column by an amount of $2\frac{1}{2}$ in., and off center on another by an amount of $1\frac{1}{2}$ in. These measurements were checked by independent observers also. In the case of two other similar columns on the same structure the load was found to be located centrally.

(2) Column No. 5 of the Equitable Building, in Des Moines[62], Iowa, showed stresses corresponding to a rotation of the lower end of the column through an angle of more than 0.001 radian.

(3) Column No. 4 of the American Insurance Union Building, at Columbus, Ohio[63], showed stresses corresponding to a rotation of the lower end of the column through an angle of 0.00138 radian.

Attention is directed to the implications of such eccentricities. In the case of all the columns shown on Figs. 28 and 29, the weight of the movable leaf was sufficient to force the column completely down to a bearing on the grillage plate. It should be noted that the errors due to milling at the base may well be duplicated at the top and that the eccentricities may act on the same side of the column, producing single curvature in the column and bending stresses at the middle (which may or may not be serious), or they may act on opposite sides of the column with resultant heavy shearing stresses. Fig. 27 illustrates this relation, showing the shears that will arise from this secondary bending at ends of members. The effect of direct column load, increasing bending and shears, is neglected. It is to be noted that the shears arising from this source alone are likely to be so heavy that they can not be taken by any reasonable amount of lacing.

It is the writer's belief, based on such information as the foregoing, that present methods of shop and field work and inspection may be expected to produce errors in end rotation of columns of 0.001 radian and that errors as large as 0.003 radian may occur easily. He would like to urge the necessity of a comprehensive investigation in shop and field of actual eccentricities occurring in structures.

The writer would also propose a special clause to cover milling for construction specifications and would suggest that definite limits to milling errors be set at an angle of 0.0005 radian and that larger errors than this be made cause for rejection. He would also call attention to the necessity for intelligent shop and field supervision in this work. Too often this work is entrusted to inspectors who have not adequate knowledge of the problem.

Local Failure.—The writer desires also to discuss briefly the question of local failure of the built-up short column and one or two factors producing such failure, together with its implications regarding the questions of column design raised in this paper. It is important to recognize that most of the models of large columns which have been tested and reported in available engineering literature have failed, not through integral action, but as a consequence of local distress. Consider, for example, the models of the second Quebec Bridge[64] having a stiffness ratio of 60 $\frac{L}{r}$, or less; or, again, consider Models $U2M1$ or $US2MS1$ of the Memphis (Tenn.) Bridge.[65] For a number of years, prominent engineers even felt that it was impossible to design short columns that would not fail locally. One investigator has stated:[66]

---

[62] *Bulletin* 72, Eng. Exp. Station, Iowa State Coll., Ames, Iowa, pp. 6 and 25, and Fig. 18.

[63] *Bulletin 40*, Eng. Exp. Station, Ohio State Univ., pp. 15, 16, 26, and Fig. 17.

> "Now if one point be clearer than any other in regard to built up columns, it is that they do not act as solid or homogeneous columns. Unless improperly designed they always fail locally by the flange buckling between panel points, and it is their strength in this connection which determines their strength as a whole. If, of course, the column deflect in a direction perpendicular to the plane of the web bracing (lacing) only, it will act as a solid column, and no question of built up column arises."

However, the integral failure of the ten models of the Metropolis (Ill.) Bridge columns may well be said to have established conclusively the fact that it is entirely practicable to design short columns that will act as a unit, and it seems obvious to the writer that, until knowledge and practice of designing main section, end connections, transverse bracing, and other features too often considered as secondary details, is such that local failure is avoided, it is futile to rely upon any theory of integral action in column design. To illustrate, the failure of Model $U2M1$ of the Memphis Bridge, through local failure of the forked ends, at a unit stress 25% below the yield point of the material, is probably a good indication of the strength of the forked ends, but not necessarily any criterion as to the strength of the member as a whole. The writer wishes to urge the proposition that the rational design of steel columns must necessarily include the design of any construction feature the premature failure of which can precipitate the collapse of the main member. There are a number of features of this class which are not adequately treated in design specifications at the present time. Prominent among them are: (1) Lateral bracing in the plane normal to the plane of the main webs of a column, this bracing commonly being composed of lacing at present; (2) the question of the proper relation between the size and stiffness of main flange angles and the web-plates; and, (3) the form of section as influenced by Factors (1) and (2).

With regard to the matter of lacing the writer feels strongly that a complete revision of present practice is urgent. He wishes to call attention to the following propositions:

(*a*) A column is subject to bending in the plane normal to the main webs, often quite as much as in the plane of the webs. Lacing does not form a proper element to resist this bending;

(*b*) Lacing on columns at present is usually much overloaded and the design loads specified are frequently about 50% of total stress carried; and

(*c*) As used at present, lacing induces serious deformations on the webs of the columns at splices, internal diaphragms, or other points of rigid support of the webs, with a direct material lowering of utilizable capacity of the main member.

---

[65] *Technologic Paper No. 101*, National Bureau of Standards, U. S. Dept. of Commerce.

[66] "Columns", by E. H. Salmon, 1921, p. 185.

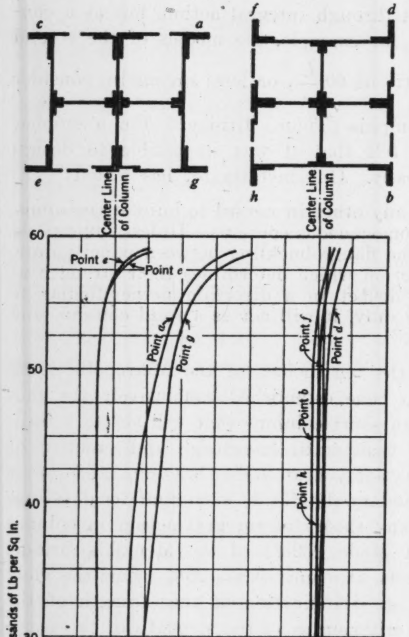

FIG. 30.

The foregoing propositions will be considered in the order listed. In view of the relative flexibility of a system of lacing, as compared with a solid plate, it seems evident to the writer that the latter is essential in order to develop the maximum efficiency of a short column. To illustrate this point Fig. 30 shows the curves for deflection normal and parallel to main webs, of Model *U2U3* of the Municipal (St. Louis, Mo.) Bridge. It will be noted that at the useful limit point of the column (namely, about 50 000 lb per sq in.), the lateral deflection in the plane of lacing is about five times that in a direction parallel to the main webs. It is also to be noted that in the case of Models *HC*1 and *MY*1 of the Metropolis Bridge[67] that the deflection at failure in the plane of the lacing, even with the solid plate in the section, is much larger than the deflection in the plane parallel to the main webs. Furthermore, most lacing is liable to abuse in handling, shipping, and erecting; it is inherently weak as a structural detail in that it is connected at the ends with one or two rivets. The difficulties arising from the failure of lacing are too well known to require much discussion.[68] The collapse at Panama, in 1915, during the official test, and under a smaller load than that for which it was designed, of the new 280-ton floating crane built for the Federal Government, was caused by such failure of lacing. With lacing replaced by a solid central plate normal to the main webs, the effect of a loose rivet or two would not be serious.

---

[67] *Technologic Paper No. 101*, National Bureau of Standards, U. S. Dept. of Commerce. Figs. 50 and 51.

[68] *Engineering News*, Vol. 73, May, 13, 1915, p. 918.

Present practice is to ignore completely the "participation" stresses induced in lacing, particularly double lacing, by deformation of the main column material under stress. Measurements on test models have shown that the lacing-bars adjacent to tie-plates, splice-plates, etc., are subjected to heavy induced stresses and, in fact, that these frequently exceed the stresses from transverse shears. In addition, the lacing on portal columns of through bridges is subjected to the shears arising from lateral loads on the structure which frequently are neglected in the design of the lacing. As a result, the lacing, at present, is often subjected to about twice the load for which it is designed. However, the main objection to present practice in lacing, from the writer's viewpoint, is that it induces distortions in the main column material at certain points and thus precipitates local failure of the member at a lower load than the material would otherwise carry. Lacing-bars acting as a pantograph, tend to force out of line the ribs of the column to which they are connected as the main material distorts axially under primary load. At points where the ribs are held rigidly in place, as at tie-plates, internal diaphragms, splice-plates, etc., this movement is prevented, but at the first connection adjacent to these points of support the lacing-bars are more or less free to move and, consequently, the distortion of the main material is greatest at these points. Careful measurement both of this movement and of the stresses induced in the webs of the column by it was made in connection with the tests on the models for the new Quebec Bridge.[69] The stresses in the main material at these points were found to be from 10 to 14% greater than elsewhere, and it is probable that the maximum stress was still greater since it was not possible to measure the stress at the sharp point of the local buckle. The number of test models of large built-up columns that fail locally as a result of this action is proportionately large. Conversely, the ten models of the Metropolis Bridge were remarkably free from local failure, and all were braced with substantial lacing supplied with transverse ties at the ends of the lacing, and all included, in the section, central longitudinal web-plate normal to the main webs. An interesting piece of evidence in this matter is afforded by the results of tests on Models *TC*4, *TC*5, and *TC*6, of the 1912 Quebec tests,[70] in which the introduction of a central diaphragm plate in the section apparently increased the capacity of the members about 18 per cent. It is to be noted that in the case of Model *U*2*U*3, of the Municipal Bridge, local failure through lacing distortion was present; and yet the model developed a high percentage of efficiency. The presence of the central longitudinal diaphragm undoubtedly contributed very materially to this result.

In view of all the foregoing considerations, the writer would propose that solid plates or diaphragms centrally located, and normal to the main web-plates, be required on all main structural steel columns having a stiffness ratio of $60 \frac{L}{r}$, or less, and that preference be given the use of a solid plate instead of lacing wherever possible. Furthermore, he would propose that all lacing on main structural columns be supplied with transverse ties at all end connections to prevent lateral displacement of the main webs, and that all such lacing be proportioned to carry the additional stress induced by this arrangement. He would further favor a more definite requirement in the specifications that all lacing and transverse webs on columns subject to lateral stresses be proportioned for such additional loads. The induced stresses in the lacing are easily and quickly computed.[71] Distribution of shears between the lacing and the solid plate when both are used should rest on a rational basis of relative rigidity of the two systems considered as a truss or a beam over the length of the member.

---

[69] Final Rept. of Board of Engrs.. Quebec Bridge, Vol. 1, pp. 207–208.

[70] *Loc. cit.*, pp. 201–209.

The use of the aforementioned features is well established by precedent. Columns of this type were used throughout on the Metropolis Bridge and on the Kansas City Bridge over the Missouri River. This type of lacing was also reported to have been used in 1914 on the Hoang Ho Bridge, in China.[72] The writer has also used the foregoing features on several fairly large highway bridges. He was pleased to find that the shop foremen reported that the tie-bars were an advantage in assembling the material and that no particular difficulty was encountered with either the lacing or with the central diaphragm. For smaller structures rolled or built-up I-beam sections, with solid webs, will often prove very suitable.

In the writer's judgment, present specifications regarding the relative proportions of flange angles to web are entirely inadequate. The real importance of this matter should not be overlooked. The chords of the first Quebec Bridge[73] were built of material having an elastic limit of about 40 000 lb per sq in., and they were designed originally to take a working stress of 24 000 lb per sq in. and, later, computed to take a working stress of 27 000 lb per sq in. The bridge chords failed at an estimated stress of 18 000 lb per sq in.[74] The first models[75], failing through inadequate lacing, collapsed at a unit stress estimated to be about 22 000 lb per sq in. The second model, adequate in lacing, failed by the buckling of webs and flange angles between lacing connections at a unit stress of about 30 000 lb per sq in. This type of failure is also evidenced in the test made by A. N. Talbot, Past-President and Hon. M. Am. Soc. C. E., and Professor H. F. Moore[76], in 1910. By analogy to the case of web-plates supported on the edges and partly supported by stiffeners in the center it is apparent that the factors involved in this problem are the relative stiffness of the plate and the angles, the length along the flange angles between lacing supports, and the width thickness ratio of the web-plates themselves. Inasmuch as the Bryan theory[77], on which the buckling theory of column web-plates rests, assumes complete support against lateral displacement of the edges of the web, it is apparent that the angles must furnish this support in addition to being stable under their own load. The writer would like to urge the advisability of adequate tests along this line, the work to begin where the web-plate tests made for the Delaware River Bridge ended.

[75] *Loc. cit.*, pp. 455–459.

[76] *Bulletin No. 44*, Univ. of Illinois Eng. Experiment Station, 1910, p. 34.

Finally, it seems to the writer that the foregoing considerations demonstrate conclusively that the form of section to be used must be taken into account when applying a column formula. The addition of a central longitudinal web-plate normal to the main webs will undoubtedly increase the unit stress that the member will carry, but will actually lower the allowable load if calculated on an $\frac{L}{r}$ basis alone, as is frequently the custom at present.

In conclusion, the writer desires to express his sincere appreciation and admiration for the remarkable work done by Mr. Young in developing a rational mathematical theory on what has been possibly the outstanding unsolved problem in structural engineering.

D. H. YOUNG,[78] JUN. AM. SOC. C. E. (by letter).—It is gratifying that the majority of the discussers are in agreement with the proposed basis for the design of steel columns as stated at the end of Section 1 of the paper. However, since some criticism of it has been made on the grounds that it is unjustifiable, it is, perhaps, worth while to recapitulate some of the considerations that led to its proposal.

First, in the case of a compressed column, it is an accepted fact that general imperfections, such as initial crookedness, accidental eccentricity of load, irregularities in cross-sectional area, and lack of homogeneity of the material, affect, considerably, the behavior of the column. It is also well known that the effect of such imperfections can be represented either by assuming a definite initial curvature of the column axis or by assuming a definite eccentricity of the compressive load. Thus, in discussing the behavior of actual columns under load, it is not only justifiable, but absolutely essential, to make one of the foregoing assumptions to allow for the effect of general imperfections, regardless of how indeterminate the proper degree of initial curvature or eccentricity of load may be. Such an assumption is a far more fundamental point than being "merely a method of applying a variable factor of safety" as Mr. Osgood calls it.

Accepting the logic of this assumption, the second step is to consider the general behavior of a pin-ended, initially curved, steel column under the action of a gradually increasing compressive load (see Fig. 4). Such a column begins to deflect laterally from the beginning of loading, and at a certain value of the compressive load yielding begins in the extreme fibers at the cross-section of greatest bending moment. This beginning of yielding may be termed a "localized failure" of the material and the corresponding value of the compressive load denoted by P_y. As the load continues to increase above the value of P_y it soon reaches a value at which the column buckles; that is, continues to bend laterally, without further increase of load. This condition may be termed "complete failure" of the column, and the corresponding load, P_u, is the ultimate load that the column can carry. In considering whether P_y or P_u should be taken as a basis for the selection of the working load for a steel column, the writer chose P_y for the following reasons:

---

[77] "Problems Concerning Elastic Stability in Structures", by S. Timoshenko, *Transactions*, Am. Soc. C. E., Vol. 94 (1930), pp. 1010–1014.

[78] Instr., Eng. Mechanics, Univ. of Michigan, Ann Arbor, Mich.

(1) The beginning of yielding represents a definite damage to the material, if not complete failure of the column, and the load, P_y, which causes such damage may well be regarded as the limit of structurally useful strength of the column. That the Engineering Profession is well agreed on this point is evidenced by the fact that it is accepted practice to select the working loads for beams, subject to transverse loading, on the basis of that loading which first produces yielding in the extreme fibers of the beam.

(2) The determination of the ultimate load, P_u, necessitates a complicated analysis involving the properties of the material beyond the proportional limit (as ordinarily defined). The degree of accuracy with which these properties can be known is not very high and, as a result, calculations of the ultimate load, P_u, are of more academic than practical value.

(3) For most cases of actual steel columns initial imperfections must be expected of such an order of magnitude that there is no great difference between the ultimate load, P_u, and the load P_y, at which yielding first begins in extreme fibers.

When Mr. Osgood criticizes the proposed basis for design on the grounds that "it results in excessive safety for short columns, * * *, and it makes the H-section appear stronger than the rectangular section, * * *", he is using as a definition of strength the ultimate buckling load, P_u. The writer believes that, to be consistent, Mr. Osgood should object also to the present, well accepted basis for the design of steel beams, subjected to transverse loading. In this case, also, current design methods make the I-section appear stronger than the rectangular section when judged on a basis of ultimate strength. In fact, this difference is even greater in the case of beams than in the case of columns.

Finally, in calculating the load, P_y, the writer assumes the material to follow Hooke's law up to the yield-point stress. In his discussion, Mr. Osgood concludes that "it is entirely unjustifiable, therefore, to assume the ideal stress-strain diagram of Fig. 2 in explaining the behavior of columns, except possibly at large values of the eccentricity ratio." As a matter of fact, there is good justification for this assumption on two counts:

(1) The writer concludes from Fig. 8 that the "large values of the eccentricity ratio", to which Mr. Osgood refers, are probably never greater than $\frac{\Delta}{k} = 0.1$. Indeterminate as the factor, Δ, may be, there is good indication that (except, possibly, for very short columns, $\frac{L}{r} < 40$, which always fail

at $\frac{P}{A} = f_y$) general imperfections necessitating an allowance for $\frac{\Delta}{k} > 0.1$ must be expected in the case of actual columns.

(2) As pointed out by Professor Turneaure, in his discussion, "the variation in yield point and in the form of the stress-strain curve in the vicinity of this point, * * * renders a more exact treatment * * * of little practical value for structural columns."

Development of Rational Design Formulas.—Following the proposed basis, rational design formulas are developed in the paper for the case of a pin-ended column under two conditions of loading: (1) The condition of loading considered in Section 2 of the paper, which is simply that of two compressive end loads; and (2) the condition of loading, considered in the first part of Section 4 of the paper, which is that of compressive end loads applied with given (not accidental) eccentricities, e_0 and e_1. For Condition (1) it is most convenient to allow for the effects of general imperfections by assuming an initial shape of the column axis in the form of a half-sine wave having a maximum deviation from a straight line through the ends of Δ. The resulting formula for determining the loading which first produces yielding is represented by Equation (12). For Condition (2) it is most convenient to allow for the effect of general imperfections by increasing the given eccentricities, e_0 and e_1, algebraically by equal amounts, e. The resulting formulas for determining the loading which first produces yielding are represented by Equation (19) and Equation (22). As mentioned by Professor Niles, design formulas can be derived by the same procedure for other conditions of loading, for example, such as a combination of axial and transverse loads.

Considerable discussion hinged upon the writer's choice of $\Delta = \frac{L}{400}$, to allow for the effect of general imperfections in the fundamental case of a pin-ended column. One finds, among the discussions, suggested values ranging from $\frac{L}{1\,200}$, as given by Mr. Gray, to $\frac{L}{300}$ as given by Mr. Godfrey. The writer chose $\frac{L}{400}$ from a study of recommendations given by various experimental investigators. Professor Turneaure suggests that this value seems too severe and points out that, as a result of its studies, the Special Committee of the Society on Steel Column Research adopted a crookedness value which corresponds approximately to $\Delta = \frac{L}{1\,200}$. It must be kept in mind, however, that the value, $\Delta = \frac{L}{400}$, as chosen by the writer, is intended to allow, not only for crookedness, but also for accidental eccentricity of load, variations in cross-sectional area, and all imperfections in general. For the most part, the Committee used special bearing-blocks by which eccentricity of load could be controlled and, hence, no conclusions can be made from such tests, regarding the possible extent of accidental eccentricities of load in the case of columns in actual structures. The writer agrees with Mr. Wyly that a careful study conducted, not only in the laboratory, but also in the field and shop, is necessary for determining the proper allowance for the effect of general imperfections. Mr. Wyly's discussion shows clearly the variety of factors which must be considered in the adoption of a reasonable value for such a factor as Δ. Particularly does it show that initial crookedness is by no means the predominate factor among general imperfections and that errors in alignment, etc., may result in very high accidental eccentricities of load. Thus, the writer does not believe that his proposal of $\Delta = \frac{L}{400}$ is by any means ultra-conservative. Mr. Wyly, however, presents good evidence to the effect that the value taken for Δ should include a constant term plus a term that increases with the length, L.

Rational Formulas vs. Empirical Formulas.—Equation (12) will serve as a basis for a comparison between rational and empirical design formulas of the straight-line and parabolic types. The principal advantage of the rational formula is that it shows explicitly what factors affect the strength of a column and, in addition, just what effect each factor has. For example, Equation (12) shows the strength of a pin-ended steel column to depend upon the following factors: (*a*) Properties of the material, as represented by f_y and E; (*b*) the extent of general imperfections, as represented by Δ; (*c*) the slenderness of the column, $\frac{L}{r}$; and (*d*) the shape of the cross-section, as defined by the core radius, k, as compared with the radius of gyration, r.

The only argument ever advanced against the rational formula is that it is cumbersome to use in practice. Regarding empirical design formulas, it is beyond question that the only argument in their favor is their simplicity.

As to the arguments against them the writer can do no better than to refer to the discussion by Mr. Durant, with which he is in complete agreement. To Mr. Durant's arguments against the empirical formula, one more may be worthy of addition; namely, that there is a definite psychological advantage in having the designer work directly with a rational formula which, like Equation (12), for example, keeps him constantly reminded of the various factors that influence the strength of the column with which he is dealing. In this way he may be able to take advantage, whenever possible, of favorable conditions regarding one or another of the aforementioned factors and thus make some saving in material or improvement in design. On the other hand, if he works day after day with a straight-line or parabolic type of formula in which $\frac{L}{r}$ appears to be the only factor affecting the strength of a column, he may soon forget the general characteristics of column action and, particularly, the inherent uncertainties which go with it.

Columns with Other Than Pinned Ends.—Regarding the adaptation of Equation (12) to the case of a column with other than pin-ended conditions of support, the writer agrees with Messrs. Sturm and Holt and with Mr.

Hartmann that this can be done by using in Equation (12) a modified value of s_e, as given by Equation (86). This is an important point since it extends considerably the range of application of Equation (12). Furthermore, it is a point that was not stressed in the paper, and it is well that these discussions have called attention to it. However, as a general method of dealing with columns having other than pin-ended conditions of support it has its definite limitations and since these limitations were not mentioned by the discussers it is, perhaps, worth while to call attention to them.

To begin with, such a procedure evidently takes for granted that when yielding first begins in the extreme fibers, the column axis will have such inflection points that the "free length" between them will be equal to the reduced length, $L' = \frac{L}{N}$, as determined by Equation (86). In general, this circumstance will be realized only by virtue of the existence of two conditions. The first is that, to allow for the effect of general imperfections, one assumes an initial shape of the axis of the column which agrees in form with the configuration of elastic buckling consistent with the constraints. Only by virtue of such an initial shape, will the "free length" between inflection points remain constant during loading and equal to the effective length, $L' = \frac{L}{N}$. In view of the highly indeterminate nature of general imperfections, it seems justifiable in any case to assume such an initial shape, thus fulfilling the first condition in effect if not in fact. The second condition which must be realized is that, during loading, any moments arising at points of constraint must be independent of change in length of the column due to compression, because, regardless of the choice of an initial shape, if such secondary moments do arise they will cause the "free length" between inflection points to change gradually during loading. For such cases it is not justifiable to use a reduced length, $L' = \frac{L}{N}$, in Equation (12), in calculating the load that first produces yielding.

In summary, the use in Equation (12) of a modified value of s_e, as given by Equation (86), for the calculation of the load first producing yielding in the case of a column with other than pin-ended supports will be justifiable: (*a*) For all cases of columns in which the manner of support is such that the constraints are of an inelastic nature (see Fig. 31); and (*b*) for columns with elastic constraints, providing the arrangement is such that bending of the column, during loading, is independent of any change in its length due to compression (see Fig. 32). The same procedure will be unjustifiable for columns with elastic constraints where the arrangement is such that bending of the column, during loading, depends upon change in its length due to compression (see Fig. 33). Cases such as those shown in Fig. 33 represent column action in rigid-frame construction and require special consideration.

The writer does not agree with Professor Turneaure that any allowance in the form of a reduced length equal to 85% of the true length should be made for possible end constraint due to friction in the case of pin-ended columns. Such a procedure might be justifiable if all loads on a pin-connected structure were static, but in the case of bridges, subjected to moving loads, vibrations of the structure are certain to be set up and such vibrations

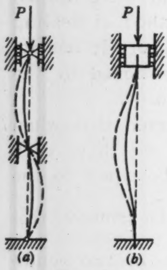

FIG. 31.

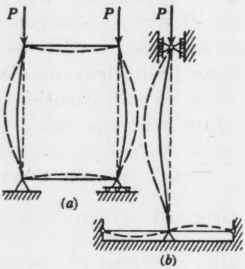

FIG. 32.

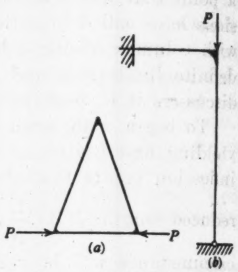

FIG. 33.

can easily result in a gradual rotational creep of the ends of a pin-ended compression member. Thus, it seems that frictional constraint at the ends of a pin-ended column is too uncertain a factor to justify any advantage being taken of it and that under certain conditions a pin-ended column designed on the basis of Equation (94) may by no means have the intended factor of safety.

Columns in Rigid Frame Construction.—It is pointed out in the paper that an exact analysis of column action in rigid-frame construction is too laborious to be practicable. Instead, it is proposed to calculate all secondary end moments by the usual approximate method and then to use Equation (19) and Equation (22), or curves, such as those of Fig. 12, plotted from these equations, as a basis for design. Such a procedure amounts to the assumption that the effective length of the member is the same as its true length and also that the secondary end moments increase in direct proportion to the axial compressive force in the member. Both these assumptions are conservative and hence the use of Equations (19) and (22), or curves like those of Fig. 12 plotted from them must, of course, result in some extra safety. However, in many practical cases, this indeterminate degree of extra safety is by no means always as large as might be expected. For example, in the case of a truss, the chord members are usually much more rigid than the web members. As a result of this the effective length of a web member will be considerably less than its true length. On the other hand, web members are usually bent in double curvature so that the maximum fiber stress occurs at one end and the member can be designed on the basis of Equation (19) where no question of effective length is involved. Again, as emphasized by Mr. Durant, chord members receive little constraint from the web members, and their effective lengths are approximately their geometric lengths. This is particularly true when one considers the behavior of a chord member in a plane perpendicular to the plane of the truss. Thus, in such cases, there is little to prevent bending of the chord members in alternate directions in successive panels. This raises the question as to whether or not the Special Committee on Steel Column Research is justified in its selection of an effective length equal to 75% of the geometric length for all cases of compression members in a riveted truss.

Built-Up Columns.—Regarding the strength of a built-up column as a unit (that is, assuming adequate lacing, diaphragms, etc.), Equation (12) can be used as a basis for design by introducing the fictitious length, L', as given by Equation (27) or Equation (28). In this case, the fictitious length, L', is greater than the true length, L, thus compensating for the additional flexibility of the column due to shearing deformation of the lacing or battens.

Regarding the proportioning of details, such as lacing or batten bars, to make certain that the built-up column will act as an integral unit, Mr. Wyly raises considerable objection to present specifications regarding this point. The writer believes that a proper basis for the design of such details is presented in Part II of the paper. The manner of allowing for the effect of general imperfections, as regards shear, is discussed in the second half of Section 5, and corresponding design formulas (Equations (33) and (39)) are developed in Sections 6 and 7. The manner of allowing for shear due to secondary end moments which occur in the case of a column in a truss, is discussed fully in Section 8, and Equation (45) is proposed as a basis for design. It is seen that in the case of a short column under the most unfavorable conditions, both as to general imperfections and secondary end moments, the necessary allowance for shear may be so high as to prohibit the use of a column of non-solid cross-section.

Mr. Durant points out that to be perfectly rigorous in the derivation of the equations of Sections 6, 7, and 8 of the paper, the writer should have used as the basic differential equation of the elastic curve, Equation (97), instead of Equation (96). Although this is true the writer believes that the error in the average shear stress, v_y, as given by Equations (33), (39), and (45), can be somewhat compensated for by using, in these equations, or in the curves plotted from them, the fictitious length, L', as given by Equation (27) or by Equation (28). Incidentally, the error appears to be on the side of safety.

Miscellaneous.—Messrs. Sturm and Holt attempt to extend the range of application of Equation (12) to the determination of the inelastic buckling load by the use of a reduced Eulerian value, s', as defined by their Equations (83), (84), and (85). However, they give no justification for such a procedure, except that values of s_u, calculated from their Equations (87) and (88) agreed "satisfactorily" with certain test results[47]. The principal obstacle to the use, in Equation (12), of a reduced Eulerian value, s'_e, calculated by the use of a reduced tangent modulus, is that such a substitution (see Equation (87)) amounts to the assumption that the material throughout the full length of the column behaves in accordance with this reduced modulus, whereas this inelastic behavior is usually confined to a relatively short portion of the length of the column.

Mr. Hartmann proposes a column formula (Equation (108)), the use of which he advocates in actual design. Mr. Hartmann's exceedingly careful definition of the factor of safety, n, scarcely seems consistent with the manner in which, subsequently, he illustrated the application of this formula. The writer cannot agree that Equation (108), when used as Mr. Hartmann advises, bears any similarity to the basis of design proposed in the paper.

[47] "Strength of Tubing Under Combined Axial and Transverse Loading", by L. B. Tuckerman, S. N. Petrenko, and C. D. Johnson, Technical Notes of National Advisory Comm. for Aeronautics, No. 307, June, 1929.

Professor Niles shows how the equations in Sections 4 and 8 can be simplified somewhat for practical use by retaining in them the variable, x_m, which defines the position of the section of maximum bending moment. His Equations (54) to (58) should prove useful to any one who desires to plot sets of curves like those of Figs. 12 and 18.

Mr. Hartmann questions the comparison made in Fig. 16 between the writer's equations for allowance for shear in a pin-ended column and the 1925 A. R. E. A. Specification. He assumes that the factor of safety has been overlooked and suggests that values of $\frac{v_y}{n}$ instead of v_y should have been plotted, which would have had the effect of lowering all the writer's curves considerably. As a matter of fact, what the writer did was to double all ordinates of the straight line representing the A. R. E. A. Specification on the assumption that it intended a factor of safety of approximately two. This surely is equivalent to Mr. Hartmann's suggestion.

In closing, it is worthy of notice, as brought out by Professor Baker, that a rational column formula, including the effect of all factors in Equation (12), except that of the shape of the cross-section, has been incorporated in the British Standard Specification for the Use of Structural Steel in Buildings and that a British Steel Structures Research Committee is considering the problem of steel columns subjected to secondary end moments, as in the case of compression members in rigid frame construction. It is hoped that this paper may have some influence in bringing the design of steel columns in the United States to a more rational basis than is represented by present-day practice. The writer agrees completely with Mr. Gray in his statement that the paper "touches only lightly on the subject", but he agrees also with Mr. Godfrey in that "its attack is in the right direction."

ANALYSIS OF THICK ARCH DAMS, INCLUDING ABUTMENT YIELD

BY PHILIP CRAVITZ,[1] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. I. M. NELIDOV, A. FLORIS, AND PHILIP CRAVITZ.

SYNOPSIS

A graphical solution of stresses in a circular arch under the influence of normal loads is presented herein. These curves differ from those previously published, in that they include the effect of abutment yield. Furthermore, a finite value for Poisson's number is used rather than the infinite value previously assumed for simplication.

Although no novel method of analyzing arches is introduced, the derivation of the final stress equations is traced because it combines advances made by Cain, Jakobsen, Vogt, and others. The forms of the equations are greatly altered, in order to facilitate computations and the plotting of graphs.

Some examination is made to determine the quantitative effect of variations in the necessary assumptions of the values of the modulus of elasticity of rock, and Poisson's number. An example of the use of the curves is appended.

INTRODUCTION

In the past several years, great strides toward a more rational solution of the stresses in an arch dam have been made by numerous contributors. Of necessity, the authors of these papers assumed either fixed or hinged-end conditions, and precise mathematical relations were built up on this basis. In an effort to consolidate the gains made in this particular field of indeterminates, F. H. Fowler, M. Am. Soc. C. E., prepared a series of graphs,[2] from which the stresses at the critical sections of crown and abutment may be obtained. That such a graphical procedure is necessary for general practical use may be

[2] "A Graphic Method of Determining Stresses in Circular Arches under Normal Loads by the Cain Formulas," by F. H. Fowler, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 1513.

verified easily by examining the complex equations arising from the mathematical treatment.

For relatively thin arches, the assumed end conditions do not introduce an appreciable error. However, it is generally recognized that, for relatively thick arches, the assumptions give stresses that can only be considered as approximate.

That the final reliance in the design of such a structure as an arch dam must rest upon the judgment of an experienced designer can scarcely be gainsaid. However, although an exact solution of the stresses in so statically an indeterminate structure is almost never to be hoped for, the judgment of the designer can be assisted more adequately by an analysis that includes all the known factors of the same magnitude of importance than by one that neglects one or two such factors.

Quantitatively, light was first shed on the bothersome subject of abutment yield by Fredrik Vogt, Assoc. M. Am. Soc. C. E., in 1924, and again in 1927.[3] Unfortunately, the stress equations arising from the inclusion of this factor and Poission's effect, are many times more unwieldy and impractical for general design use than the equations that exclude these factors. That the complexity of these equations should be mastered is evidenced by the fact that, in many instances, there may be a possible saving of concrete when the arch is analyzed on the basis of yielding abutments, because of the more equable distribution of stress between crown and abutment.

Discussion of the division of load between cantilevers and arches is not pertinent to this paper because it was possible to construct the graphs so that the curves would be applicable regardless of the proportion of water load determined, or assumed, to be carried by the arches. Wherever possible, detailed derivation is eliminated and reference is made to the origin.

Notation.—In the notation advanced herein (see Appendix), an effort has been made to reconcile the conflicting symbols introduced by several writers, with the American Standard Symbols for Mechanics, Structural Engineering, and Testing Materials.[4]

DERIVATION OF STRESS EQUATIONS

Arch Ring Deformations.—Using the customary sign conventions (that is, linear deformations are positive when they are elongations; stresses are positive when they produce a positive deformation; and, water pressure, p_e, is taken as positive), Cain and Jakobsen derive the relation for an arch ring, shown in Fig. 1,[5] as follows:

$$\Delta_C = X \left\{ \frac{r^2_n}{E_e I_n} \left[r_C (\phi_1 - \sin \phi_1) - r_n \left(\sin \phi_1 - \frac{\phi_1}{2} - \frac{\sin 2 \phi_1}{4} \right) \right] + \frac{r_n}{E_c t} \left[1.94 \phi_1 - 0.47 \sin 2 \phi_1 \right] \right\} - \frac{\sigma}{E_c t} p_e r_e r_n \sin \phi_1 \ldots\ldots (1)$$

The following pertinent relations also are derived:

$$M = X\,(r_C - r_n \cos\,\phi) \ldots\ldots\ldots\ldots\ldots\ldots(3)$$

$$N = p_e\,r_e - X \cos\,\phi \ldots\ldots\ldots\ldots\ldots\ldots(4)$$

and,

$$V = X \sin\,\phi \ldots\ldots\ldots\ldots\ldots\ldots(5)$$

in which, M, N, and V are the moment, thrust, and shear, respectively, at any arbitrary section at an angle, ϕ, from the crown.

Foundation Deformations.—Although the ideal case, upon which Professor Vogt's foundation deformation equations are based,[*] can never be exactly attained in practice, the quantitative information derived is probably correct within a usable range of accuracy. A gratifying check on his theoretical and empirical forms has been made by the Committee of Engineering Foundation on Arch Dam Investigation.[*]

In Fig. 2, Professor Vogt presents a hypothetical cantilever of length, l, and thickness, t. In plan, the loaded area is equal to h. Under the influence of the load, $w\,h$ (assuming plane sections to remain plane), any deformation of the foundation may be resolved into the components, Δ_{n1}, Δ_v, and ψ. In terms of N_1, V_1, and M_1, at the base, their values are as follows:

---

[*] Rept. by the Committee of Engineering Foundation on Arch Dam Investigation, Vol. II, May, 1934, pp. 225 to 232, inclusive.

$$\Delta_N = \frac{m^2 - 1}{m^2} \times \frac{N_1}{E_R\, t} \times \sqrt[3]{t^2 h} \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

$$\Delta_V = \frac{m^2 - 1}{m^2} \times \frac{V_1}{E_R\, t} \times \sqrt[3]{t^2 h} + \frac{(m-2)(m+1)}{m^2} \times \frac{M_1}{E_R\, t} \times \frac{1}{1 + 1.1\,\dfrac{t}{h}} \ldots (7)$$

and,

$$\psi = \frac{18}{\pi} \times \frac{m^2 - 1}{m^2} \times \frac{M_1}{E_R\, t^2} \times \frac{1}{1 + 0.25\,\dfrac{t}{h}} + \frac{(m-2)(m+1)}{m^2}$$

$$\times \frac{V_1}{E_R\, t} \times \frac{1}{1 + 1.1\,\dfrac{t}{h}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

in which, E_R = the modulus of elasticity of rock; $N_1 = w \sin \alpha$ = normal force per unit of length; $V_1 = w \cos \alpha$ = shear force per unit of length; and $M_1 = w\, l \cos \alpha$ = moment force per unit of length.

Where the moment is referred to the center, or gravity, axis, Equations (6), (7), and (8) are reduced to;

$$\Delta_N = \zeta \times \frac{N_1}{E_R} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

$$\Delta_V = \zeta \times \frac{V_1}{E_R} + \eta\, \frac{M_1}{E_R\, t} \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

and,

$$\psi = \mu\, \frac{M_1}{E_R\, t^2} + \eta\, \frac{V_1}{E_R\, t} \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

in which the values of ζ, η, and μ are obvious by comparison.

For the arch, the moment force about the gravity line is,

$$M_1 = X\,[r_C - r \cos \phi_1] + p_e\, r_e\, c \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

and N_1 and V_1 are the same as N and V in Equations (4) and (5), respectively. Inserting these values of N_1, V_1, and M_1, into Equations (6), (7), and (8), and taking the components of Δ_N and Δ_V normal to the crown radius, the foundation yield would allow a crown-section movement of:

$$\Delta_F = \frac{\zeta}{E_R}\,[V_1 \sin \phi_1 - N_1 \cos \phi_1] + \eta\, \frac{M_1}{E_R\, t} \sin \phi_1$$

$$+ \left[\mu\, \frac{M_1}{E_R\, t^2} + \eta\, \frac{V_1}{E_R\, l}\right] [r_n\,(1 - \cos \phi_1) - c \cos \phi_1] \ldots\ldots\ldots (13)$$

or, expanded and re-arranged:

$$\Delta_F = \frac{X}{E_R}\left[\zeta - \eta\, \frac{r}{t} \cos \phi_1 \sin \phi_1 - \left(\mu\, \frac{r}{t} \cos \phi_1\right)\left(\frac{r_n}{t} - \frac{r}{t} \cos \phi_1\right)\right.$$

$$+ \eta \sin \phi_1 \left(\frac{r_n}{t} - \frac{r}{t} \cos \phi_1\right)\Bigg] + \frac{X\, r_C}{E_R} \left[\frac{\eta}{t} \sin \phi_1 + \frac{\mu}{t} \left(\frac{r_n}{t} - \frac{r}{t} \cos \phi_1\right)\right]$$

$$+ \frac{p_e\, r_e}{E_R} \left[\eta \frac{c}{t} \sin \phi_1 - \zeta \cos \phi_1 + \mu \frac{c}{t} \left(\frac{r_n}{t} - \frac{r}{t} \cos \phi_1\right)\right] \ldots .(14)$$

and,

$$\psi_F = \mu \frac{M_1}{E_R\, t^2} + \eta \frac{V_1}{E_R\, t} = \frac{X}{E_R\, t} \left(\eta \sin \phi_1 - \mu \frac{r}{t} \cos \phi_1\right)$$

$$+ \frac{X\, r_C\, \mu}{E_R\, t^2} + p_e\, r_e \frac{\mu\, c}{E_R\, t^2} \ldots\ldots\ldots\ldots\ldots\ldots .(15)$$

Derivation of Variables, K and r_C, Including Yield.—Using the two known end conditions of the crown section, due to symmetry, namely, Equations (16) and (17):

$$\Sigma\, (\Delta_C + \Delta_F) = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots .(16)$$

and,

$$\Sigma\, (\psi_C + \psi_F) = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots .(17)$$

and substituting for X the product, $K\, p_e\, r_e$, two equations are derived in terms of t, r, ϕ, m, ζ, μ, and η, and the two unknowns, K and r_C. Furthermore, it is assumed that $E_c = E_R$ and that $I_n = I = \frac{1}{12}\, t^3$. Thus:

$$\left[\sigma \frac{r_n}{t} \sin \phi_1 + \zeta \cos \phi_1 - \eta \sin \phi_1 \frac{c}{t} - \mu \frac{c}{t} \left(\frac{r_n}{t} - \frac{r}{t} \cos \phi_1\right)\right]$$

$$- K \Bigg[- 12 \left(\frac{r_n}{t}\right)^3 \left(\sin \phi_1 - \frac{\phi_1}{2} - \tfrac{1}{4} \sin 2\, \phi_1\right) + \frac{r_n}{t} (1.94\, \phi_1 - 0.47 \sin \phi_1)$$

$$+ \zeta - \eta \sin \phi_1 \frac{r}{t} \cos \phi_1 - \mu \frac{r}{t} \cos \phi_1 \left(\frac{r_n}{t} - \frac{r}{t} \cos \phi_1\right)$$

$$+ \eta \sin \phi_1 \left(\frac{r_n}{t} - \frac{r}{t} \cos \phi_1\right)\Bigg] - K \frac{r_C}{t} \Bigg[12 \left(\frac{r_n}{t}\right)^2 (\phi_1 - \sin \phi_1)$$

$$+ \eta \sin \phi_1 + \mu \left(\frac{r_n}{t} - \frac{r}{t} \cos \phi_1\right)\Bigg] = 0 \ldots\ldots\ldots .(18)$$

and,

$$K \frac{r_C}{t} \left[12 \left(\frac{r_n}{t}\right) \phi_1 + \mu\right] - K \left[12 \left(\frac{r_n}{t}\right)^2 \sin \phi_1 - \eta \sin \phi_1 + \mu \frac{r}{t} \cos \phi_1\right]$$

$$+ \left[\mu \frac{c}{t}\right] = 0 \ldots\ldots\ldots\ldots\ldots\ldots .(19)$$

The solution of Equations (18) and (19) simultaneously may be simplified greatly by a convenient grouping of variables such that:

$$Q_1 = \Biggl[- 12\left(\frac{r_n}{t}\right)^2 \left(\sin \phi_1 - \frac{\phi_1}{2} - \tfrac{1}{4} \sin 2\,\phi_1\right) + \frac{r_n}{t}\,(1.94\,\phi_1 - 0.47 \sin 2\,\phi_1)$$
$$+ \zeta - \eta \sin \phi_1 \frac{r}{t} \cos \phi_1 - \mu \frac{r}{t} \cos \phi_1 \left(\frac{r_n}{t} - \frac{r}{t} \cos \phi_1\right)$$
$$+ \eta \sin \phi_1 \left(\frac{r_n}{t} - \frac{r}{t} \cos \phi_1\right)\Biggr] \quad \ldots\ldots\ldots\ldots\ldots\ldots (20)$$

$$Q_2 = \left[12\left(\frac{r_n}{t}\right)^2 (\phi_1 - \sin \phi_1) + \eta \sin \phi_1 + \mu\left(\frac{r_n}{t} - \frac{r}{t} \cos \phi_1\right)\right] \ldots (21)$$

$$Q_3 = \left[\sigma\left(\frac{r_n}{t}\right) \sin \phi_1 + \zeta \cos \phi_1 - \eta \frac{c}{t} \sin \phi_1 - \mu \frac{c}{t}\left(\frac{r_n}{t} - \frac{r}{t} \cos \phi_1\right)\right] . (22)$$

$$Q_4 = \left[12\left(\frac{r_n}{t}\right)^2 \sin \phi_1 - \eta \sin \phi_1 + \mu\left(\frac{r}{t}\right) \cos \phi_1\right] \ldots\ldots\ldots (23)$$

$$Q_5 = \left[\mu\left(\frac{c}{t}\right)\right] \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

and,

$$Q_6 = \left[12\left(\frac{r_n}{t}\right) \phi_1 + \mu\right] \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

Substituting Equations (20) to (25) in Equations (18) and (19), the following more manageable forms are derived:

$$Q_3 - K\,Q_1 - K\,\frac{r_C}{t}\,Q_2 = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

and,

$$K\,\frac{r_C}{t}\,Q_6 - K\,Q_4 + Q_5 = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

or, solving simultaneously,

$$K = \frac{(Q_3 \times Q_6) + (Q_5 \times Q_2)}{(Q_1 \times Q_6) + (Q_4 \times Q_2)} \ldots\ldots\ldots\ldots\ldots\ldots (28)$$

and,

$$\frac{r_C}{t} = \frac{(Q_4 \times Q_3) - (Q_1 \times Q_5)}{(Q_2 \times Q_5) + (Q_3 \times Q_6)} \ldots\ldots\ldots\ldots\ldots\ldots (29)$$

Stress Equations in Terms of K and r_C.—Professor Cain has derived the equations of stress for a thick arch in the form:

At the Crown:

$$s_e = \frac{M_c}{I}\,\frac{\frac{t}{2} + c}{r_s}\,r_n - \frac{P_C}{r_e \log_e\left(\frac{r_e}{r_i}\right)} \ldots\ldots\ldots\ldots\ldots (30)$$

and,

$$s_i = -\frac{M_c}{I}\,\frac{\frac{t}{2} - c}{r_i}\,r_n - \frac{P_C}{r_i \log_e\left(\frac{r_e}{r_i}\right)} \quad \text{.............}(31)$$

At the Abutment:

$$s_e = \frac{M_1}{I}\,\frac{\frac{t}{2} + c}{r_e}\,r_n - \frac{P_1}{r_e \log_e\left(\frac{r_e}{r_i}\right)} \quad \text{.............}(32)$$

and,

$$s_i = -\frac{M_1}{I}\,\frac{\frac{t}{2} - c}{r_i}\,r_n - \frac{P_1}{r_i \log_e\left(\frac{r_e}{r_i}\right)} \quad \text{.............}(33)$$

Equations (30) to (33) may be converted into a form convenient for computing and platting by noting that,

$$\log_e\left(\frac{r_e}{r_i}\right) = \frac{t}{r_n} \text{ (approximately)} \quad \text{.................}(34)$$

$$P = p_e\,r_e - X \cos\phi \quad \text{..................................}(35)$$

$$M = X(r_C - r_n \cos\phi) \quad \text{..................................}(36)$$

$$X = p_e\,r_e\,K \quad \text{..................................}(37)$$

$$12\,\frac{r_n}{t}\left(\frac{1}{2} + \frac{c}{t}\right) = n_e \quad \text{......................}(38)$$

and,

$$12\,\frac{r_n}{t}\left(\frac{1}{2} - \frac{c}{t}\right) = n_i \quad \text{......................}(39)$$

Making the necessary substitutions, Equations (30) to (33) reduce to:

At the Crown:

$$\frac{s_e}{p_e} = n_e\left(K\,\frac{r_C}{t}\right) + \frac{r_n}{t}\,(1 - n_e)\,K - \frac{r_n}{t} \quad \text{...........}(40)$$

and,

$$\frac{s_i}{p_e} = -\frac{r_e}{r_i} \times n_i\left(K\,\frac{r_C}{t}\right) + \frac{r_e}{r_i} \times \frac{r_n}{t}\,(1 + n_i)\,K - \frac{r_e}{r_i} \times \frac{r_n}{t} \quad \text{...}(41)$$

At the Abutment:

$$\frac{s_e}{p_e} = n_e\left(K\,\frac{r_C}{t}\right) + \frac{r_n}{t}\,(1 - n_e)\,K \cos\phi_1 - \frac{r_n}{t} \quad \text{........}(42)$$

and,

$$\frac{s_t}{p_e} = -\frac{r_e}{r_i} \times n_t\left(K\frac{r_C}{t}\right) + \frac{r_e}{r_i} \times \frac{r_n}{t}(1 + n_t) K \cos \phi_1 - \frac{r_n}{t} \times \frac{r_e}{r_i} \quad ..(43)$$

EFFECT OF VARIATIONS IN E_R AND m

The equations introduced in this paper correspond with comparable equations derived by Cain with the added advantages that the effect of yielding abutments and a finite value of Poisson's ratio are taken into consideration. To simplify the use of these equations a set of graphs is necessary, similar to those presented by Fowler in 1927. Figs. 3, 4, 5, and 6 are examples of such curves. These graphs are based on the following conditions, assumptions, or simplifications: (*a*) The arch is circular and of uniform thickness; (*b*) $I_n = \frac{1}{12} t^3$; (*c*) $\frac{E_v}{E_c} \times 1.2 = 2.88$ (in which, E_v = the modulus of elasticity in shear); (*d*) the trace of the abutment plane is normal to the arch rib; (*e*) the loading over the entire arch is uniform; (*f*) the stress due to vertical loads is zero; (*g*) $E_C = E_R$; (*h*) $m = 8$; and (*i*) tensile stresses are positive.

As the values of E_R and m selected for the computations are open to conjecture, the effect of a reasonable variation from the chosen values is to be examined. The result of solving a specific example, in which the effect of abutment yield is quite appreciable (since the ratio, $\frac{t}{r}$, is large), is shown in Table 1(*a*), where the stresses when $E_R = 75\% \, E_C$ and $E_R = 125\% \, E_C$ are compared with those obtained when it is assumed that $E_R = E_C$. In this example, $t = 30$ ft; $r = 60$ ft; $2\,\phi_1 = 120°$; and $\frac{h}{t} = 2$. The values in

TABLE 1.—STRESSES (IN POUNDS PER SQUARE INCH) FOR UNIT HEAD IN AN ARCH WITH YIELDING ABUTMENTS

Variant	CROWN		ABUTMENT	
	Extrados	Intrados	Extrados	Intrados
(*a*) COMPARISON OF STRESSES FOR VARIOUS VALUES OF E_R				
$E_R = E_c$	−1.35	−0.14	−0.07	−2.18
$E_R = \frac{3}{4} E_c$	−1.34	−0.09	−0.15	−2.08
$E_R = 1\frac{1}{4} E_c$	−1.28	−0.16	−0.03	−2.25
(*b*) COMPARISON OF STRESSES FOR VARIOUS VALUES OF POISSON'S RATIO				
Fixed abutments; $m = 8$	−1.18	−0.13	+0.41	−2.77
Yielding abutments; $m = 8$	−1.35	−0.14	−0.07	−2.18
Yielding abutments; $m = 5$	−1.29	−0.18	−0.10	−2.16

Table 1(*a*) are derived with the assistance of Figs. 3(*a*), 4(*a*), 5(*a*), and 6(*a*), by first entering the charts from the bottom at the given value of $\phi = \frac{120}{2} = 60$ degrees. Then continue vertically to an intersection with the proper curve of $\frac{t}{r} = \frac{30}{60} = 0.5$. The stresses for unit head on the horizontal lines through these intersections may then be read.

The greatest variation from the assumed E_R amounts to only approximately 0.10 lb per sq in. for unit head, which, for a 100-ft head, would change the stresses by only 10 lb per sq in.

In Table 1(*b*), the stresses when $m = 5$ are compared with those when $m = 8$, the value adopted for the curves. As in the previous example, $\frac{t}{r} = 0.5$, $2\,\phi_1 = 120°$, and $\frac{h}{t} = 2$, and the stresses are derived by means of Fig. 3(*a*), 4(*a*), 5(*a*), and 6(*a*). Furthermore, in order to show the comparative effect of including abutment yield, the stresses obtained with the assumption of fixed ends, as in Fowler's curves, are included.

Table 1(*b*) indicates that the stresses are quite insensitive to fairly large variations in the value of *m*. For this typical example, furthermore, the yielding abutment calculations show a more equable distribution of stress between crown and abutment by increasing the critical crown extrados stresses and reducing the critical abutment intrados stresses. In this particular example, tension at the abutment extrados found by the fixed-end assumption is substituted by a small compression upon introducing the yielding foundations.

EXAMPLE TO DEMONSTRATE THE USE OF THE CURVES

As a typical case, assume that $\frac{h}{t} = 7$; thickness of arch, $t = 40$ ft; central radius = 100 ft; $2\,\phi_1 = 65°$; head of water = 150 ft; and that the arch carries 75% of the load. This problem is solved by determining stresses separately from Figs. 3, 4, 5, and 6, for $\frac{h}{t} = 2$ and $\frac{h}{t} = 12$. The unit-head stress for $\frac{h}{t} = 7$ is then found by interpolation. The final process is illustrated by Table 2. To obtain the arch stresses from the unit-head stress, values of unit stresses in Table 2 are multiplied by 150 × 0.75.

TABLE 2.—STRESSES (IN POUNDS PER SQUARE INCH), IN AN ARCH WITH YIELDING ABUTMENTS

Acknowledgment

The writer wishes to express his appreciation to John L. Cox, Jun. Am. Soc. C. E., for some valuable assistance rendered in checking curve computations.

APPENDIX

Notation

The following notation is recommended for the guidance of discussers:

b = breadth.

c = radial distance between the neutral axis and the gravity axis of the arch barrel; as a subscript, c, denotes "concrete."

d = depth.

e = eccentricity; as a subscript, e, denotes "extrados."

f = unit fiber stress.

h = height; approximate height of loaded abutment.

i = a subscript to denote "intrados."

k = radius of gyration.

m = Poisson's number; $\frac{1}{m}$ = Poisson's ratio.

n = a substitution factor (see Equations (38) and (39)); as a subscript, n, denotes "neutral axis."

p = pressure per unit area; p_e = normal radial pressure acting on the arch along the extrados.

r = radius; radius of the gravity axis of the arch ring; r_n = radius of the neutral axis of the arch ring; r_e = radius of extrados; r_C = radial distance along the crown radius, to the point at which it is necessary to apply Force X, in order to eliminate crown rotation.

s = stress; s_e = unit stress at the extrados; s_i = unit stress at the intrados.

t = thickness; radial thickness of the arch.

v = unit shear.

y = radial deflection.

C = constant; as a subscript, C, denotes "crown."

E = modulus of elasticity; E_c = modulus of elasticity of concrete; E_R = modulus of elasticity of rock; E_v = modulus of elasticity, E, in shear.

F = a subscript denoting "yielding foundation."

H = head.

I = rectangular moment of inertia; I_n = moment of inertia about the neutral axis.

J = polar moment of inertia.

K = a constant $= \dfrac{X}{p_e\, r_e}$.

M = moment; moment at any arbitrary section, at an angle, ϕ, from the crown; M_1 = moment, M, at the abutment.

N = thrust at any arbitrary section, at an angle, ϕ, from the crown; N_1 = normal force, N, at the abutment.

P = a concentrated load; a thrust normal to an arch section; P_C = a thrust normal to a section at the crown; P_1 = a thrust normal to a section at the abutment.

Q = a substitution factor (see Q_1, Q_2, etc.).

R = reaction; as a subscript, R, denotes "rock."

T = temperature.

V = total shear; shear at any arbitrary section, at an angle, ϕ, from the crown; V_1 = shear force, V, at the abutment.

W = total load.

X = additional crown force applied normal to the radius passing through the crown, necessary to bring the crown section back to its original position.

α = angle with the normal, or radial.

ξ = specific gravity;

Δ = deformation; Δ_C = deformation of the crown section normal to its radius; Δ_F = deformation of the crown section due to yielding foundation.

δ = unit elongation.

ϵ = coefficient of thermal expansion.

ζ = a substitution factor (see Equation (9)).

η = a substitution factor (see Equation (10)).

θ = angular distance.

μ = a substitution factor (see Equation (11)).

ρ = radius of curvature.

Σ = summation of.

σ = a correction due to Poisson's effect $= \left[\dfrac{m-1}{2\,m} + \dfrac{m+1}{2\,m}\left(\dfrac{r_t}{r_n}\right)^2\right]\dfrac{r_e}{r}$.

ϕ = a central angle; angle of any radius with the radius through the crown.

ψ = rotation of a section; ψ_C = angular rotation of the crown section from a radial line; ψ_F = angular rotation of the crown section as the result of yielding in the foundation.

DISCUSSION

I. M. Nelidov,[7] Assoc. M. Am. Soc. C. E. (by letter).—The development of the method by which the effect of abutment deformations on stresses in a circular arch ring can be estimated, is offered in this paper. The author has plotted curves for $E_r = E_c$; $m_r = m_c = 8$; and $\frac{h}{t} = 2 - 12$, so that the stresses can be determined directly as a function of $\frac{t}{r}$ and the central angle, $2\,\phi_1$. The method considers the deformation of the neutral fiber of the arch ring decreased by the effect of Poisson's ratio and by the introduction of a finite thickness of the arch. Furthermore, it is based on the assumption that plane sections remain plane after deformation. It ignores any possible interference from adjacent arch rings. As is known, the method is conventional, being derived from the use of thin railroad arches, in which the ratios of cross-sections to the length of the axial line are small. Its advantage is in the workable form of the equations. On the other hand, any attempt to introduce the effect of the finite thickness and of Poisson's ratio in the form of an interaction between the radial and tangential stresses leads to unusually complicated formulas.[8]

When an important structure is under consideration, a method based on the general equations of the theory of elasticity should be used preferably. For instance, applying such a method as that developed by C. W. Comstock,[9] M. Am. Soc. C. E., to an arch ring with $\frac{t}{r} = 0.345$ and $2\,\phi_1 = 60°$ and with $p_e = 1.0$, one finds the results indicated in Table 3(*a*). For an arch ring with $\frac{t}{r} = 0.02$ and $2\,\phi_1 = 47°$, Table 3(*b*) will give the comparative results.

It is to be noted that when the elastic properties of the material of the arch are considered there is a notable increase of tensile stresses in arches with large ratios of $\frac{t}{r}$ and small central angles. In the development of the results in Table 3 it was assumed that the plane between the adjacent arches remains a plane and that no shearing stresses occur within this plane.

Referring to the derivations of the paper, the writer wished to arrive at the author's results by following a different line of reasoning. Consider

a circular arch ring of uniform thickness, loaded with the uniform radial load. Its main, or statically determinate, system is shown in Fig. 7(*a*). For this system the moments, thrusts, and shear are known, as follows: $M' = p_e\, r_e\, e'$; $P' = -\, p_e\, r_e$; and $V' = 0$. Furthermore, in accordance with Fig. 8:

$$e' = \frac{\int_{r_i}^{r_e} \left(1 + \frac{r_i^2}{r_y^2}\right) r_y\, dr_y}{\int_{r_i}^{r_e} \left(1 + \frac{r_i^2}{r_y^2}\right) dr_y} \quad \ldots\ldots\ldots\ldots\ldots\ldots (44)$$

Equation (44)[10] indicates that the funicular frame of the loads and the neutral line of the arch are spaced at a distance, e'.

If the left abutment is fixed, as shown in Fig. 7(*b*), and the right end of the arch is supported with a rigid cantilever extending to the elastic center, *E*, three unknown redundant forces, *X*, *Y*, and *Z*, are thus introduced, which will be determined if the deformations which they should counteract are made known.

Using the general equation of elastic work and considering only the work, *W*, of the tangential and shearing stresses:

$$W = \int_{-\phi_1}^{+\phi_1} \int_{r_i}^{r_e} \tfrac{1}{2}\, s_{mt}\, dr\, \Delta_{mt}\, d\phi + \int_{-\phi_1}^{+\phi_1} \int_{r_i}^{r_e} \tfrac{1}{2}\, s_{pt}\, dr\, \Delta_{pt}\, d\phi$$

$$+ \int_{-\phi_1}^{+\phi_1} \int_{r_i}^{r_e} \tfrac{1}{2}\, s_v\, dr\, \Delta_v\, d\phi \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45)$$

in which, s_{mt} is the unit tangential stress due to bending moment; s_{pt} is the unit tangential stress due to thrust; s_v is the unit tangential stress due to shear; and, Δ is the corresponding total deformation.

---

[10] "Strength of Materials", by S. Timoshenko, Pt. II, p. 532, 1931 Edition.

The unit stresses in a cross-section and the corresponding deformations are shown in Fig. 8. This stress and deformation distribution is modified near the supports by the influence of the deformation of abutments, but to an unknown extent.

The unit tangential stress due to water pressure and the force, X, will be:

$$s_{pt} = \frac{P\, r_n}{t\, r_y} = \frac{-\,p_e\, r_e + X \cos\phi\; r_n}{t r_y} \quad\text{..............(46)}$$

and the uniform deformation due to this stress is expressed by the equation:

$$\Delta_{pt} = -\,\frac{p_e\, r_e\, r_n}{E_c\, t}\,\sigma + \frac{X\cos\phi\; r_n}{E_c\, t} \quad\text{................(47)}$$

in which $\sigma = \frac{r_e}{2\,r}\left[1 + \frac{r_i^2}{r_n^2} - \frac{1}{m}\left(1 - \frac{r_i^2}{r_n^2}\right)\right]$.

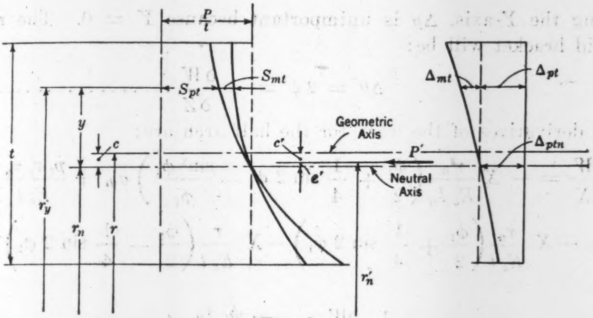

FIG. 8.

The unit tangential stress due to the bending moment produced by the water pressure and the force, X, will be:

$$s_{mt} = -\frac{p_e\,r_e}{t}\left[\frac{r_n}{r_y} - \frac{r_e}{2\,r}\left(1 + \frac{r^2_i}{r^2_y}\right)\right]$$

$$+\left[X\,r_n\left(\cos\phi - \frac{\sin\ \phi_1}{\phi_1}\right) + Z\right]\frac{r_n}{I_n}\left(\frac{r_n}{r_y} - 1\right)\ldots\ldots\ldots\ldots\ldots(48)$$

and the total deformation due to this stress is expressed by:

$$\Delta_{mt} = \frac{-\,p_e\,r^2_e\,r_y}{2\;tr\;E_c}\left[1 + \frac{r^2_i}{r^2_y} - \frac{1}{m}\left(1 - \frac{r^2_i}{r^2_y}\right)\right] + \frac{p_e\,r_e\,r_n}{Et}\,\sigma$$

$$+\left[X\,r_n\left(\cos\phi - \frac{\sin\ \phi_1}{\phi_1}\right) + Z\right]\frac{r_n}{E_c\,I_n}\left(\frac{r_n}{r_n} - 1\right)r_y\ \ldots\ldots(49)$$

In accordance with Fig. 7(b), the total stresses in a section are:

$$M = M' + X\,y + Z\ldots\ldots\ldots\ldots\ldots\ldots(50a)$$

$$P = P' + X\cos\phi\ldots\ldots\ldots\ldots\ldots\ldots(50b)$$

and,

$$V = 0 + X\sin\phi\ldots\ldots\ldots\ldots\ldots\ldots(50c)$$

It is noted that as with $\phi = 0$, and $V = 0$, the force, $Y = 0$, and does not enter in Equations (50).

The relative displacement of the End $E\ C$ of the rigid bracket directed along the X-axis will be in accordance with Fig. 7(c) and Fig. 7(d):

$$\Delta x = \Delta x_1 + \Delta x_2 = 2\,\Delta_N\cos\phi_1 - 2\,\Delta_T\sin\phi_1 - 2\,\psi\left(r_n\,\frac{\sin\phi_1}{\phi_1} - r\cos\phi_1\right)$$

$$= -\frac{\partial W}{\partial X}\ \ldots\ldots\ldots\ldots\ldots\ldots\ldots(51)$$

Along the Y-axis, Δy is unimportant because $Y = 0$. The rotation of the rigid bracket will be:

$$\Delta\theta = 2\psi = -\frac{\partial W}{\partial Z} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (52)$$

The derivatives of the work for the half arch are:

$$-\frac{1}{2}\frac{\partial W}{\partial X} = -X\frac{r^3_n}{E_c I_n}\left(\frac{\phi_1}{2} + \frac{1}{4}\sin 2\phi_1 - \frac{\sin^2\phi_1}{\phi_1}\right)\sigma_m + \frac{p_e r_e r_n}{E_c t}\sin\phi_1\,\sigma_p$$
$$-X\frac{r_n}{E_c t}\left(\frac{\phi_1}{2} + \frac{1}{4}\sin 2\phi_1\right) - X\frac{r}{E_c t}\left(\frac{\phi_1}{2} - \frac{1}{4}\sin 2\phi_1\right)\sigma_v \ldots (53a)$$

and,

$$-\frac{1}{2}\frac{\partial W}{\partial Z} = -Z\frac{\phi_1 r_n}{E_c I_n}\sigma'_m \ldots\ldots\ldots\ldots\ldots\ldots\ldots (53b)$$

The coefficients, σ, in Equations (52) and (53) are: $\sigma m = \sigma m' = 1$; $\sigma_p = \frac{1+\sigma}{2}$; and $\sigma v = 2.88$. In deriving these coefficients all the factors producing less than 1% of the divergence of the stress were omitted.

With the sign convention adopted the normal and tangential displacements and rotation of the abutment will be:

$$\Delta_N = \zeta\frac{P_1}{E_r} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (54a)$$

$$\Delta_V = -\zeta\frac{V_1}{E_r} + \eta\frac{M_{1g}}{E_r t} \ldots\ldots\ldots\ldots\ldots\ldots (54b)$$

and,

$$\psi = -\eta\frac{V_1}{E_r t} + \mu\frac{M_{1g}}{E_r t^2} \ldots\ldots\ldots\ldots\ldots\ldots (54c)$$

in which $M_{1g} = -p_e r_e c' + X\left(r\cos\phi_1 - r_n\frac{\sin\phi_1}{\phi_1}\right) + Z$. Due to the small influence of e', $c' = c$ will be assumed in future operations.

After substitution of Equations (50) and (53) into Equations (51) and (52) and subsequent integration, the following expressions are obtained for evaluating the unknowns, X and Z:

$$-p_e r_e\left\{\frac{r_n}{t}\frac{E_r}{E_c}\sin\phi_1\,\sigma_p + \zeta\cos\phi_1 - \frac{c}{t}\left[\eta\sin\phi_1 + \mu\left(\frac{r_n}{t}\frac{\sin\phi_1}{\phi_1} - \frac{r}{t}\cos\phi_1\right)\right]\right\}$$
$$+X\left\{\frac{r^3_n}{I_n}\frac{E_r}{E_c}\left(\frac{\phi_1}{2} + \frac{1}{4}\sin 2\phi_1 - \frac{\sin^2\phi_1}{\phi_1}\right) + \frac{r_n}{t}\frac{E_r}{E_c}\left(\frac{\phi_1}{2} + \frac{1}{4}\sin 2\phi_1\right)\right.$$
$$+\sigma_v\frac{r}{t}\frac{E_r}{E_c}\left(\frac{\phi_1}{2} - \frac{1}{4}\sin 2\phi_1\right) + \zeta + 2\eta\sin\phi_1\left(\frac{r_n}{t}\frac{\sin\phi_1}{\phi_1} - \frac{r}{t}\cos\phi_1\right)$$
$$\left.+\mu\frac{r_n}{t}\left(\frac{\sin\phi_1}{\phi_1} - \frac{r}{r_n}\cos\phi_1\right)\left(\frac{r_n}{t}\frac{\sin\phi_1}{\phi_1} - \frac{r}{t}\cos\phi_1\right)\right\}$$
$$-\frac{Z}{t}\left[\eta\sin\phi_1 + \mu\frac{r_n}{t}\left(\frac{\sin\phi_1}{\phi_1} - \frac{r}{r_n}\cos\phi_1\right)\right] = 0 \ldots\ldots (55a)$$

and,

$$-p_e r_e \mu \frac{c}{t} - X\left[\eta \sin \phi_1 + \mu \frac{r_n}{t}\left(\frac{\sin \phi_1}{\phi_1} - \frac{r}{r_n} \cos \phi_1\right)\right]$$

$$+ \frac{Z}{t}\left[\mu + \phi_1 \frac{E_r}{E_c} \frac{r_n}{I_n} t^2\right] = 0 \ldots\ldots\ldots\ldots\ldots (55b)$$

Equations (53) can be rewritten as follows:

$$A + B K + C K_1 = 0 \ldots\ldots\ldots\ldots\ldots\ldots (56a)$$

and,

$$A' + B' K + C' K_1 = 0 \ldots\ldots\ldots\ldots\ldots\ldots (56b)$$

in which $K = \dfrac{X}{p_e r_e}$ and $K_1 = \dfrac{Z}{p_e r_e t}$

The solution of these equations gives:

$$K = \frac{A - A' \dfrac{C}{C'}}{B' \dfrac{C}{C'} - B} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (57a)$$

and,

$$K_1 = -\frac{A' + K B'}{C'} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (57b)$$

The coefficients of Equations (57) are:

$$A = -\frac{r_n}{t} \sin \phi_1 \frac{E_r}{E_c} \sigma_p - \zeta \cos \phi_1$$

$$+ \frac{c}{t}\left[\eta \sin \phi_1 + \mu \frac{r_n}{t}\left(\frac{\sin \phi_1}{\phi_1} - \frac{r}{r_n} \cos \phi_1\right)\right] \ldots\ldots\ldots\ldots (58a)$$

$$B = \zeta + \eta\left(2 \frac{r_n}{t} \frac{\sin 2\phi_1}{\phi_1} - \frac{r}{t} \sin 2\phi_1\right)$$

$$+ \mu \left(\frac{r_n}{t}\right)^2 \left(\frac{\sin \phi_1}{\phi_1} - \frac{r}{r_n} \cos \phi_1\right)\left(\frac{\sin \phi_1}{\phi_1} - \frac{r}{r_n} \cos \phi_1\right)$$

$$+ \frac{r_n^3}{I_n} \frac{E_r}{E_c}\left(\frac{1}{2} \phi_1 + \frac{1}{4} \sin 2\phi_1 - \frac{\sin^2 \phi_1}{\phi_1}\right)$$

$$+ \frac{r_n}{t} \frac{E_r}{E_c}\left(\frac{1}{2} \phi_1 + \frac{1}{4} \sin 2\phi_1\right) + \sigma_v \frac{r}{t} \frac{E_r}{E_c}\left(\frac{1}{2} \phi_1 - \frac{1}{4} \sin 2\phi_1\right) \ldots (58b)$$

$$C = -\left[\eta \sin \phi_1 + \mu \frac{r_n}{t}\left(\frac{\sin \phi_1}{\phi_1} - \frac{r}{r_n} \cos \phi_1\right)\right] \ldots\ldots (58c)$$

$$A' = -\mu \frac{c}{t} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (58d)$$

$$B' = -\left[\eta \sin \phi_1 + \frac{r_n}{t}\left(\frac{\sin \phi_1}{\phi_1} - \frac{r}{r_n} \cos \phi_1\right)\right] \ldots\ldots\ldots (58e)$$

and,

$$C' = \mu + \phi_1 \frac{E_r\, r_n}{E_c\, I_n}\, t^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (58f)$$

Equations (58) may be checked against Equations (18) to (25) of the paper by noting that Equation (52) is $-\psi = \phi_1 \frac{r_n}{E_c I_n} Z$, and by comparing Equation (50a) with Equation (3) of the paper, from which it follows that $Z = X\left(r_n \frac{\sin \phi_1}{\phi_1} - r_c\right)$. After substituting these expressions into Equations (51), (52), and (53), Equations (18) to (25) of the paper are obtained.

A question of the relative importance of Poisson's ratio and of the deformation of abutments arises. Table 4 shows a comparison of stresses, in pounds per square inch, for p_e = 1 lb and for arch rings varying from a very thin arch, with a very large central angle, to a very thick arch with a very small central angle. Table 4 also gives the percentage of divergence of stresses from those computed by a conventional method; that is, with small $\frac{t}{r}$; with $m_c = \infty$; and with rigid abutments.

TABLE 4.—COMPARISON OF STRESSES
(Tension is Positive)

* Finite. † Reversal of sign.

The unit stresses in Table 4 were computed by the combined expressions, Equations (46) and (48). The bending stress due to water pressure expressed by the first part of Equation (48) is numerically equal to ±0.20 lb per sq in. for the arch, with $\frac{t}{r}$ = 0.15, and to ±0.07 lb per sq in. for the arch, with $\frac{t}{r} = 0.50$. This stress is of minor importance at the crown, but it is of significance at the abutment, if considered.

The data in Table 4 indicate that in an arch ring of an average thickness and with an average central angle the divergence of stresses is about 10%, and only the deformation of abutments causes a greater divergence. For a thick arch ring with small central angle, the divergence due to Poisson's ratio is about 20%, whereas that due to the deformation of abutments is increased many times this amount. The divergence of shearing stresses is negligible.

The limits of the ratio, $\frac{h}{t} = 1 - 30$, were assumed, in order to visualize the effect of the extremely large deformations, although actually this ratio will never be greater than 1. It was originally applied by Fredrik Vogt, Assoc. M. Am. Soc. C. E., for the case of an abutment of constant thickness, t, and with the forces, M, P, and V, uniformly distributed along the height, h. In the case of an arch dam this condition is not fulfilled; both the thickness, t, and the acting forces vary along the height, h, producing a warped surface of an original abutment plane (which is ordinarily a warped surface from the start, due to the requirements of the excavation).

The problem becomes complex and a practical issue for its solution must be found. If the arch rings of a unit height, as well as the areas near the abutment were separate one from another, then under the forces acting they would displace in relation to each other, as the keys of a piano, each one an independent element. The relative elasticity and continuity of the foundation makes the deformation spread to the neighboring units over a certain distance. From a list of seventy-four arch dams in California the writer found that the ratio, $\frac{h}{t} = \frac{1}{t}$, at the crest varied from 0.046 to 1.000 (average 0.200) and at the base from 0.009 to 1.000 (average 0.042). If the entire height of the dam was assumed as h, the same ratios would be: At the crest between 2 and 45 (average, 16); and, at the base, between 1.4 and 19 (average, 5). As the deformation coefficients, ζ, η, and μ, increase with $\frac{h}{t}$, the selection of larger values of $\frac{h}{t}$ will be on the side of safety; but even with an increase of five to ten times the ratios referred to, h will be only about equal to 1. The ratios in which the entire height of the dam is considered do not seem to be justified.

A. **Floris**, Esq.[11] (by letter).—The title of this practical paper and the introductory remarks made therein, are rather misleading, because the plotting of curves is not an analysis or graphical solution of a problem. The author utilizes a known theory by arranging its results in the form of diagrams for use in practice. From this point of view, of course, the paper is a valuable addition to the literature on the subject.

---

[11] Dipl. Ing., Los Angeles, Calif.

The usefulness of graphs would be greatly increased if they were made independent of the system of units. The author's diagrams, and those for arches with fixed abutments, referred to in the paper, have a common drawback. They cannot be utilized in countries in which the metric system of units is used. It is possible, however, to arrange the diagrams in such a way, as to make them independent of this restriction. N. Kelen, in his well-known book on arch and multiple-arch dams, for instance, gives graphs that can be used independently of the system of units.[12]

It would be appreciated if the author could include in his closing discussion, graphs that do not have the aforementioned restrictions. If this is not feasible, a brief outline demonstration of how such graphs are plotted would be a welcome addition.

PHILIP CRAVITZ,[13] JUN. AM. SOC. C. E. (by letter).—In an engineering paper involving such ponderous equations as those concocted by the writer, it is indeed satisfying to him to obtain a verification of his basic equations by an independent method such as that provided by Mr. Nelidov. That the more laborious general equations of elasticity should preferably be used in the design of important structures, as is stated by Mr. Nelidov, is a debatable matter of opinion. It can scarcely be denied that an exact solution for an actual case in practice can probably never be obtained, because there are always such factors as the irregularity of the dam site, dissymmetry relative to any given center line, variations in the properties of the abutments when traversed from side to side, etc.

Because of such practical considerations, the writer believes that an exact theoretical solution may prove more bothersome, and scarcely more reliable, than a method which strives to consider all stress factors of equal magnitude of importance plus the judgment of an experienced design engineer. The curves presented in the paper do enable a designer to visualize quantitatively the effect of yielding abutments on stresses in thick arch dams. However, because of the basic fact that the stresses of a statically indeterminate structure, such as an arch dam, are fundamentally independent of the scale, regardless of the number of stress determinants that are considered, there must be some mathematical set-up, similar to that devised by the writer, in which the final equations vary with $\frac{t}{r}$ and $2\,\phi_1$. Thus, it is only a question of regimenting computations so as to evolve curves that give stresses for any number of contributing factors introducing the slightest variation in the resultant stresses.

Regarding the desire expressed by Mr. Floris to obtain the curves in a universal system of units, it may be sufficient to indicate that the stresses given by the curves may be easily converted to any other desired system by the multiplication of a constant. For example, to obtain the stresses, in kilograms per square centimeter, multiply all values obtained from the curves by 0.23 times the height of water head, in meters.

ELASTIC PROPERTIES OF RIVETED CONNECTIONS

BY J. CHARLES RATHBUN,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. RALPH E. GOODWIN, HAROLD C. ROWAN, WALTER SCHOLTZ, J. F. BAKER, L. E. GRINTER, C. R. YOUNG AND K. B. JACKSON, E. MIRABELLI, R. L. MOORE, JOHN SANFORD PECK, AND J. CHARLES RATHBUN.

SYNOPSIS

In designing floor-beams for steel-frame buildings, it is customary to neglect the restraining effect of end connections and to assume that the beams are hinged at the ends. In many other problems of stress analysis in steel frames, it is customary to treat the connections as completely fixed, or rigid.

While it is recognized that the end connections do provide some degree of restraint there has been no means of allowing for it because no one has known, numerically, how much restraint there is. One could not safely take advantage of any saving resulting from the resistance due to bending, created by the connections.

Tests of eighteen end connections of the three most common types of steel beams, form the basis of this paper.[2] The writer has shown how these data may be applied in the design, not only of single beams, but also in the investigation of the stresses in frames, composed of beams and columns, joined by these typical riveted connections.

His analysis shows that economics in design can be effected safely in some cases. It also gives the engineer a more complete understanding of the action of standard beam connections, and indicates several problems for further research.

NOTE.—Published in January, 1935, *Proceedings*.

INTRODUCTION

The purpose of this paper is to record data derived from a series of tests of standard riveted beam connections and to show the method of incorporating this information in the analysis of steel frames. These tests were conducted in the Materials Testing Laboratory of the School of Technology of the College of the City of New York. Some idea is afforded of the rigidity of several types of connections and of the effect of yielding in these connections on the stress distribution in steel structures, such as building frames.

All the so-called "exact methods" of solution of the building frame under loads are based on the assumption (among others) that the horizontal members are rigidly connected to the vertical. This may lead to serious error. Unlike the assumption that the members do not change in length under stress, the effect of yielding in the connections cannot be determined by the analyst alone. Laboratory experiments are necessary in order to establish constants to incorporate into any analysis that may be made.

Little has been published on this important subject; to date, only a few isolated tests have been made on riveted connections for the purpose of obtaining some measure of their capacity to resist moment. In 1917, a series of tests was made at the University of Illinois, Urbana, Ill.[3] C. R. Young, M. Am. Soc. C. E., has conducted tests at the University of Toronto, Toronto, Ont., Canada, primarily for the purpose of comparing riveted, with welded, connections.[4] The writer knows of no other tests, at all extensive, on the subject.

Although it is probable that many of the connections encountered in a wind-stress design of buildings will be larger than those represented in the data herein submitted, the results of this investigation should serve as a guide in evaluating the properties of the larger connections. The capacity of the testing machine limited the size of the specimens tested.

The paper consists of two parts: Part I is a report on a series of physical tests to determine the relationship between the angular change in riveted beam connections and the moment inducing these changes; and Part II shows the necessary changes that must be made in the formulas used in the several current methods of analysis in order to allow for the elasticity of the riveted connections.

PART I.—PHYSICAL TESTS ON RIVETED CONNECTIONS

TEST SPECIMENS

Ordinary shop practice was followed in fabricating the specimens used in this work, no special care being taken because of the fact that the specimens were to be subjected to tests.

The physical properties of the steel in the various specimens of these tests are given in Table 1.

DESCRIPTION OF TEST SPECIMENS

Eighteen specimens (see Figs. 1 and 2) representing as many connections were tested for the purpose of furnishing data from which their elastic resistance to moment could be obtained. These specimens may be divided into three types: Series *A*, Specimens 1 to 7 (Fig. 1), are standard clip-angle connections; Series *B*, Specimens 8 to 12 (Fig. 1) are seat-angle connections; and Series *C*, Specimens 13 to 17 (Figs. 1 and 2) are a series of shallow wind-braced connections. Specimen 18 was designed to furnish some information on the effect of the post on the joint. In Series *A* and *B*, $\frac{7}{8}$-in. rivets were driven in $\frac{15}{16}$-in. holes. In Series *C*, except Specimens 13 and 14, 1-in. rivets were driven in $1\frac{1}{16}$-in. holes. The lighter pieces were punched and the heavier ones were drilled.

Each specimen consisted of a central plate with an I-beam abutting on either side fastened by means of the standard connection to be investigated. The specimen thus formed was tested by applying a load on the central plate, while it was supported at the outer ends of the I-beams. Thus, the specimen acted as a simple beam loaded at the center and a known moment was induced in the two connections.

Series *A* represents a type of connection that is not designed primarily to resist moment, and it is customary to consider these connections as hinged. However, they have some measure of elasticity and it was hoped that these tests would furnish the data necessary to enable a designer to estimate this elasticity in those cases where it seriously affected stress distribution. In designing Series *A*, standard connections were chosen from those published in Handbooks issued by steel manufacturers, taking the double-riveted connections and the companion single-riveted connections for the 8-in., 12-in., and 18.-in. I-beams. Thus, a study of double riveting as it affected the stiffness of the connections was made. The spread in size from the 8-in. to the 18-in. I-beams was as great as was considered practicable. As the 6-in. standard connection is probably the most common, it was added to the series. A comparison of the several connections showing the effect of adding a second row of rivets can be made by studying Fig. 3.

FIG. 2.—TEST SPECIMENS OF RIVETED CONNECTIONS, WITH 1-IN. ϕ-RIVETS. SERIES C.

Series *B* was designed and tested in order to find the stiffening effect of seat angles. Owing to the superior lever arm of these angles over those in Series *A*, these connections proved to be comparatively stiff (see Fig. 3 (*a*)). Although it is not common practice to place seat angles at both the top and bottom of the I-beam, it was thought that a better balanced connection for the purpose of these tests would be thus obtained. A variation from common practice was made in the width of the angles and in the combination of seat angles and clip angles. From a comparison of the curves thus obtained (see Fig. 3 (*a*)), it is hoped that one can form some estimate of these several factors.

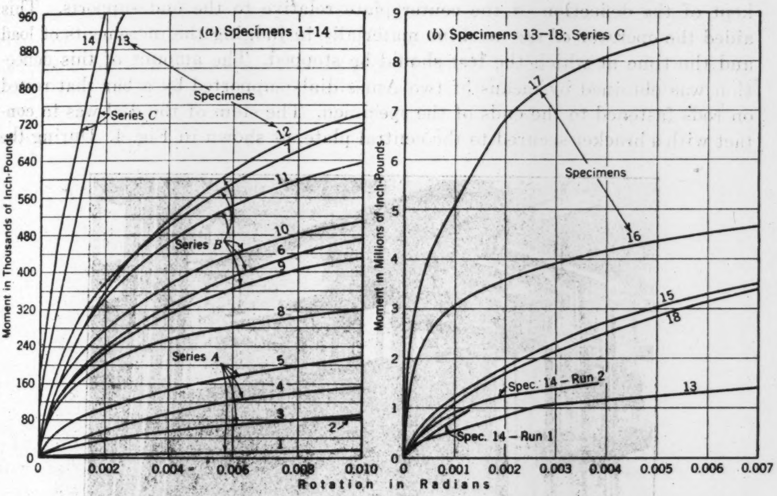

FIG. 3.—COMPARATIVE ELASTICITY OF CONNECTIONS.

Series *C* (Fig. 3 (*b*)) represents one type, and a common one, of shallow wind-braced connections. No definite standards were available, so the writer designed these units. Specimen 13 was designed so that the failure due to tension in the rivets might be anticipated and that, before such a failure would occur, the shear rivets would be badly overstressed. In Specimen 14 the tension rivets were increased in number over those in Specimen 13. Specimen 15 was a re-design of Specimen 13 for heavier construction, and Specimen 18 is a companion to Specimen 15. The comparison of these two should give some idea of the effect of inserting a post in place of the plate. Specimens 16 and 17 were designed to permit a study of the effect of a double row of tension rivets. The members in this entire series are graded in size from the small 12-in. I-beam to a specimen as large as could be handled in the laboratories.

METHOD OF TESTING

The specimens in which the anticipated load was less than 60 000 lb were tested in a screw machine of that capacity. An I-beam was laid on the bed of the machine in order to support the bearing-blocks; the load was applied at the rate of 0.05 in, per min; and the machine was kept in balance, but the load was not increased, while the readings were being taken. For specimens in which the anticipated load was greater than the capacity of the 60 000-lb machine the tests were made in a hydraulic machine of 300 000-lb capacity, and the bed was extended as before. The supporting beam was from the same stock as the specimen and deflection readings on it permitted a comparison between the beam and the connection.

All the specimens were whitewashed so as to accentuate strain lines and deformation in the rivets and plates. During each test, a careful record was kept of the deflection of the center plate relative to the end supports. This aided the operator of the machine materially in judging the increments of load and the time at which the test should be stopped. The amount of this deflection was obtained by means of two Ames dials supported by a bar that rested on rods fastened to the ends of the specimen. The stem of the dial was in contact with a bracket secured to the central plate, as shown in Fig. 4. During the test the average of the two dial readings was plotted, but the resulting curve has not been incorporated in this paper; nor has it been used in computing the accompanying curves. For such a curve to be of value, corrections would have to be made for the shear deformation of the joint and for the elastic deformation of the beam itself. Although these corrections are appreciable, the dials proved advantageous for the purpose intended. For the tests of Series *A* and *B* the side bars were brass, $\frac{1}{4}$ in. by 1 in. in cross-section; and for Series *C* and Specimen 18, a 3-in. duralumin channel was used.

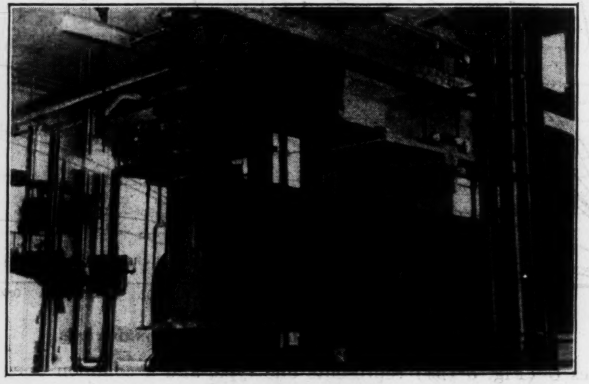

FIG. 4.—SPECIMEN 16, SHOWING POSITION OF THE SEVERAL DIALS AND METHOD OF BRACING A SPECIMEN AGAINST BUCKLING.

For a simple beam under uniform load, with a deflection of $\frac{1}{360}$ of its span, the angle of rotation of the end of the beam is about 0.009 radian. When possible, the tests were continued until the deflection of the connection exceeded this value. In a few cases this was prevented by the limited capacity of the machine.

Four dials, reading to 0.0001 in., were used in obtaining the angular rotation of each connection. In the case of Series *A* they were clamped directly to the flange of the I-beam with their stems resting against the central plate. This type of set-up could not be used in the remaining tests. In the case of Series *B*, the seat angles were in the way of the clamps, and, as some shear would occur between these angles and the I-beam, a different design was required. The flanges of the stubs of the I-beam in Series *C* interfered with the stem of the dial, and, in addition, the web of the stub interfered with the clamps as in Series *B*. The special holder shown in Fig. 5 was made to carry the dials in Series *B* and *C*. It was designed to furnish a three-point contact when clamped between the flanges of the I-beam. As first designed the pointed screws of the holder were made solid, but this proved unsatisfactory because the beam deformed under stress, causing one point to become loose. To correct this difficulty the points were placed on springs, as shown in Fig. 5(*b*).

(*b*) Section at Points

(*c*) Extensions for 16- and 22-in. Beams

FIG. 5.—SPECIAL DEVICE FOR HOLDING DIALS THAT MEASURED ROTATION OF CONNECTION

In the tests of Series *B* the stems of the dials rested directly on the control plate. In the tests involving the stub I-beams (Series *C*, and Specimen 18), the stems of the dials could not be brought in direct contact with the central plate, so steel bands of iron (1 in. by $\frac{1}{8}$ in.), were placed around the stubs and secured to the plate by set screws at the elevations where the dial stems would come in contact with them (see Figs. 4 and 6(*c*)). Care was taken that the bands did not touch any part of the specimen except through the set screws, thus assuring the condition that they were stationary relative to the plate.

In Series *B* and *C*, another set of dials was secured to the flange of the I-beam, but back of the connection, as shown in Figs. 4, 6(*b*), and 6(*c*). Readings from these dials were for the purpose of securing data that would be of value if an accident occurred to any of the other rotation dials during the test. The data thus obtained have not been incorporated in this paper. Fig. 6 shows schematically the location of the various dials and the general set-up of the tests.

DESCRIPTION OF TESTS AND FAILURES

Each specimen was tested by loading it on the central plate, thus inducing a moment of one-fourth the load times the span and a shear of one-half the load in each connection. Fig. 7(*a*) illustrates the manner in which connec-

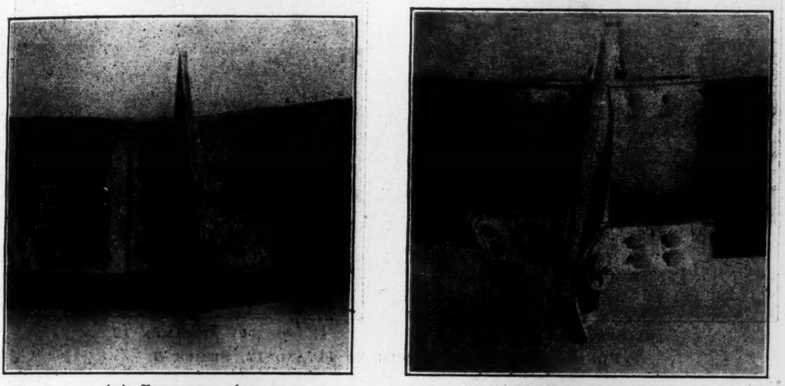
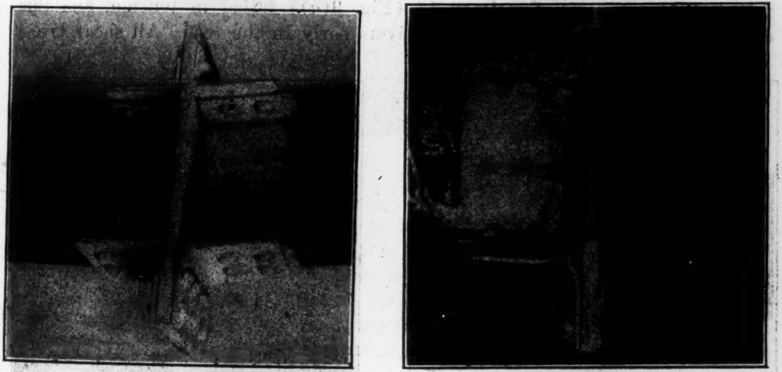
tions in Series *A* failed. The angles deformed badly without visible distress in the rivets or in the I-beams. The tests seem to confirm the general impression that this type of connection can be subjected to considerable angular deformation without seriously affecting the capacity of the connection to take shear.



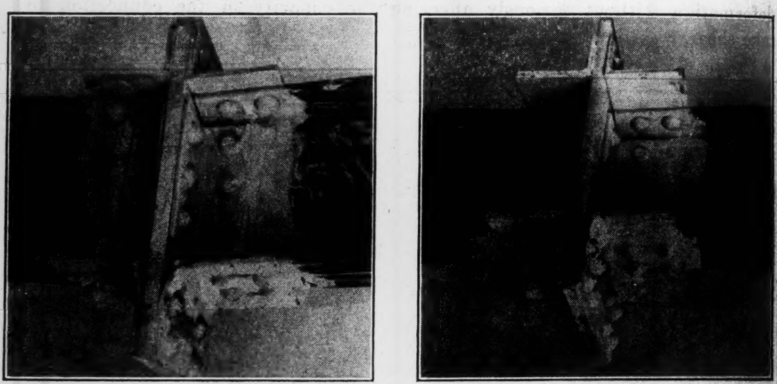
(*a*) SPECIMEN 4. (*b*) SPECIMEN 8.



(*c*) SPECIMEN 9. (*d*) SPECIMEN 10.

FIG. 7.—TYPES OF FAILURES, SERIES *A* AND *B*.

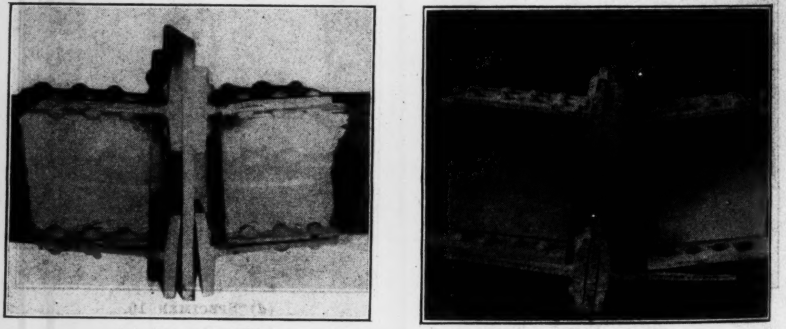
Figs. 7(*b*), 7(*c*), and 7(*d*) illustrate the manner in which the three types studied in Series *B* failed. Compared with Fig. 7(*d*), Fig. 7(*b*) shows the peculiar effect of widening the seat angles, whereas Fig. 7(*c*) shows the combination of seat and clip angles. It is to be noted that the serious stresses, apparently, are confined to the lower seat angles, and in some cases to the rivets in the lower seat angles, but not to the I-beams. From this, it might be inferred that the connection can be stiffened materially by increasing the thickness of the angles. (In the test specimens in all cases these angles are $\frac{5}{8}$ in.) However, for a given deformation, this would lead to an increased unit stress. The effect of lengthening the seat angle may be noted by comparing the failure of Specimen 11 with that of Specimen 12, in Fig. 8.



(a) SPECIMEN 11. (b) SPECIMEN 12.

FIG. 8.—FAILURE OF SPECIMENS 11 AND 12, SERIES *B*.

Figs. 4, 9, and 10 illustrate the manner in which specimens of Series *C* failed. The rivets in Specimen 13 (Fig. 9(*a*)) failed in tension, and this connection showed weakness in the rivets early in the test. All shear rivets showed a considerable deformation and, doubtless, if the previous failure in the tension rivets had not occurred, the connection would have failed in horizontal shear, with a slight increase of load. The flanges of the I-beams indicated distress long before the failure. In Fig. 9(*a*) the deformation due to shear on the connection, as well as that due to moment, is quite evident.



(a) SPECIMEN 13. (b) SPECIMEN 15.

FIG. 9.—FAILURES OF SPECIMENS 13 AND 15, SERIES *C*.

Specimen 15 (Figs. 2 and 9(*b*)) was a case of direct shear failure. Some tensile deformation of the rivets was clearly visible and the flanges of the stub I-beam on the tension side were deformed. This connection failed suddenly. Specimen 16 (Fig. 2) failed by tension in the rivets, with some small deformation of the flanges of the I-beam, whereas in Specimen 17 (Fig. 2), there was no visible deformation under the load of 300 000 lb, the limiting capacity of the machine.

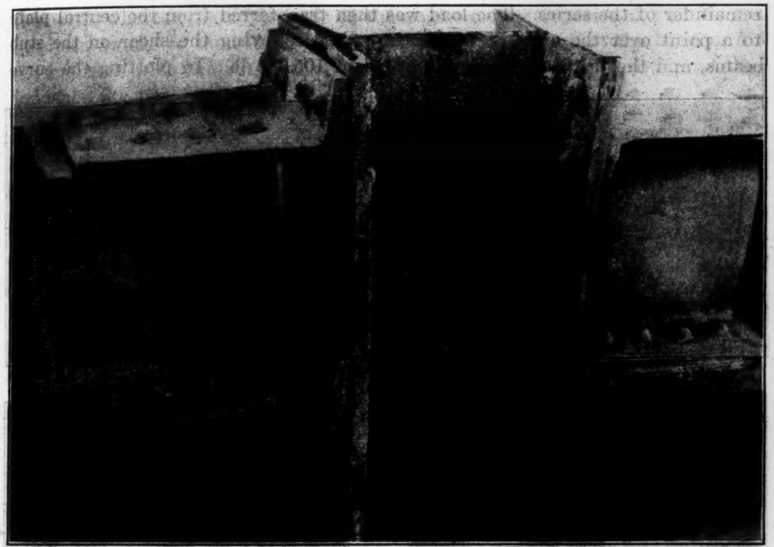


Fig. 10.—Failure of Specimen 18.

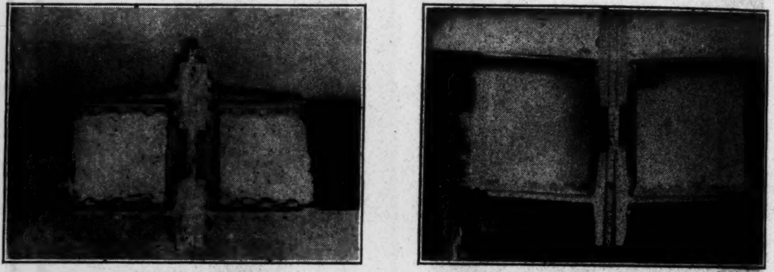
Sundry other failures of beams in Series *C* are illustrated in Fig. 11. The lines of shear in the I-beam of Fig. 11(*a*), are clearly visible, as is also the affect of the rivet heads due to shear. This test gave no visible evidence of tension in the rivets. The method of placing dials for the specimens of Series *C*, is shown in Fig. 11(*b*). Another view (Specimen 15) of the shallow wind-bracing connection, after the rivets had failed in shear, is shown in Fig. 11(*c*). In Fig. 11(*d*), Specimen 16 reveals distress in shear as well as rivets that have failed in tension.

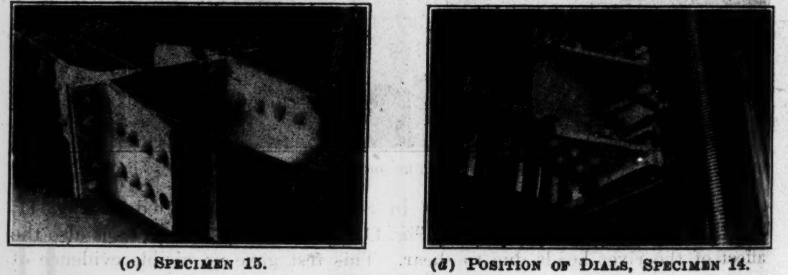
Specimen 18 (Fig. 2) failed in a manner so complicated that it is difficult to compare the results of this test with those of its companion, Specimen 15. The column section showed distress before the connections had passed their yield point. From Fig. 10 one can follow the general action of this joint. The stress distribution in tension was high in the central rivets and low in the outer ones.

The column section used was so short that the curves obtained do not properly represent the effect due to a column of considerable length. The difference in the curves of Specimens 15 and 18 is probably greater than would be produced by the usual column section found in practice.

In Specimen 14 there was little distress evident due to rivet tension. Deformation due to shear on the rivets was visible and strain lines on the I-beam indicated that the connections had passed their limit of working stress. In testing this specimen, experience with Specimen 13 led the writer to anticipate a shear failure. After obtaining the stress reading for a load of 80 000 lb, the load was removed. This gave a set of curves that compare with the remainder of the series. The load was then transferred from the central plate to a point over the ends of the I-beam, thus relieving the shear on the stub beams, and the test was re-run to a load of 105 000 lb. In plotting the curve of the second run the effect of a decrease in the length of the lever arm was taken into consideration. The point of zero deflection was observed with no load on the beam; it was not read as the deflection due to the set from the previous load. Failure did not occur in the connections of this specimen but at one of the supports, where the I-beam buckled.



(a) Specimen 14. (b) Specimen 16.



(c) Specimen 15. (d) Position of Dials, Specimen 14.

Fig. 11.—Failures of Specimens 14, 15, and 16, Series C.

As the specimen had not been destroyed, except for the buckling of one flange of the I-beam, it was inverted and replaced in the machine in order that a study of the reversal of stresses might be obtained. In this third run on the specimen the loads were placed over the ends of the I-beam and not on the central plate, primarily because this edge of the plate had not been milled for this type of loading. The curve obtained was of an entirely different type from that of the others in this entire series of tests. This curve suggests a subject for further investigation.

In the case of the test of Specimens 15, 16, and 17, difficulty was encountered because of the tendency of the specimen to buckle (see Fig. 4). Stiffening angles were welded at the ends of the supporting beam, and similar angles were clamped to the ends of the specimen. In addition, angles were bolted on either side of the specimen. These angles were braced to the building to prevent a failure due to the upper ends of one of these sets of angles swinging to the north, whereas the upper ends of the angles on the opposite end of the test specimen swung to the south. Care was taken to ensure that the bracing did not interfere with the rotation of the test specimen on its supports, and thus influence the test readings.

METHOD OF COMPUTING ROTATION

The rotation of the beam relative to the plate was measured by means of Dials *E* to *L* in Fig. 6(*b*) to Fig. 6(*d*). The rotation of each connection was obtained by noting the difference in reading between the two dials on one side of the I-beam and dividing it by the distance between the two dial stems. The corresponding dials on the opposite side of the I-beam furnished a second set of observations on this same point. The readings on the second connection of the specimen were obtained in a similar manner and the two sets of observations on each connection were averaged. Thus, each test may be considered as a test of two connections, one on the right side, and one on the left side, of the plate. These two tests were practically independent of each other, except for some slight deformation of the central plate.

In order that the variation between the two tests may be seen, the curves showing the angular rotation plotted against the moment have been drawn for both connections in Figs. 12 to 23. The average is plotted in full and, from this curve, the data in Table 2 are taken. The angle of rotation is expressed in radians or, what is the same thing, as its tangent, and the moment is expressed in inch-pounds. It is to be noted that all the curves are of the same general shape and have no definite yield point. This is more clearly shown in Series *A* and *B* than in Series *C*.

Reloading curves were taken during the tests, but in order to avoid confusion, only the curve of the average between the two connections has been plotted. These reloading curves are quite straight, and elastic constants for the connections have been obtained from their slopes.

Table 2 gives two constants for each type of connection tested, taken from the average curve. Column (2) gives the slope of the curve at its origin for a connection that has not been previously strained. Column (3) gives the slope of the reloading curves. All these slopes are in inch-pounds. The ultimate moment imposed on the connections is given in Column (4) except in the cases indicated, in which the capacity of the machine or other cause prevented carrying the test to failure.

SHEAR

In the method of testing used, the shear effect and the moment effect were not entirely separated from each other. This was not considered a serious

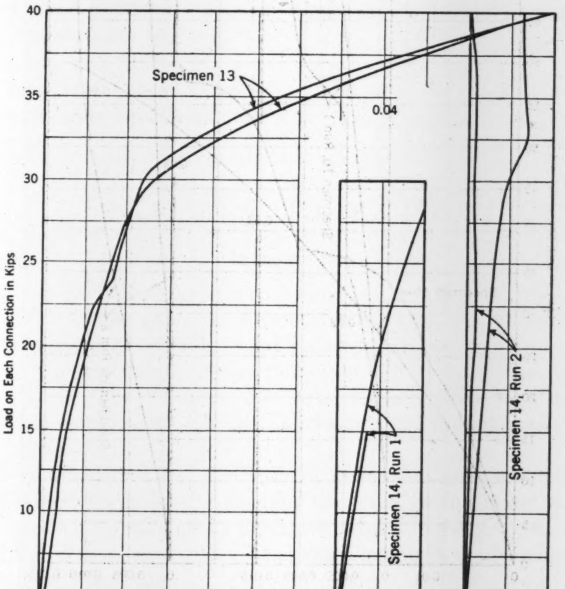

FIG. 24.—DEFORMATION DUE TO SHEAR, SPECIMENS 13 AND 14.
SERIES C.

objection as they have little effect on each other as far as deformation is concerned, especially in the range of working stress. In actual practice both shear and moment are present in a connection when under stress. In all the tests an effort was made to obtain stress-deformation curves for the connection in shear. For Series *A* and *B* the results were not considered of much practical value and are not given in this paper. The shear stresses were low and the results were not satisfactory. The connections were designed to resist shear, but not moment. In Series *C,* however, very interesting data were obtained, which lead one to believe that this type of connection is much more satisfactory in shear than has heretofore been supposed. In no specimen of this series was special provision made for shear. Although it was seriously questioned whether these connections could take enough shear to produce ultimate failure in moment, it was thought that adding clip angles would complicate the interpretation of the results. The series of tests was designed as a study of the effect of moment and not of shear.

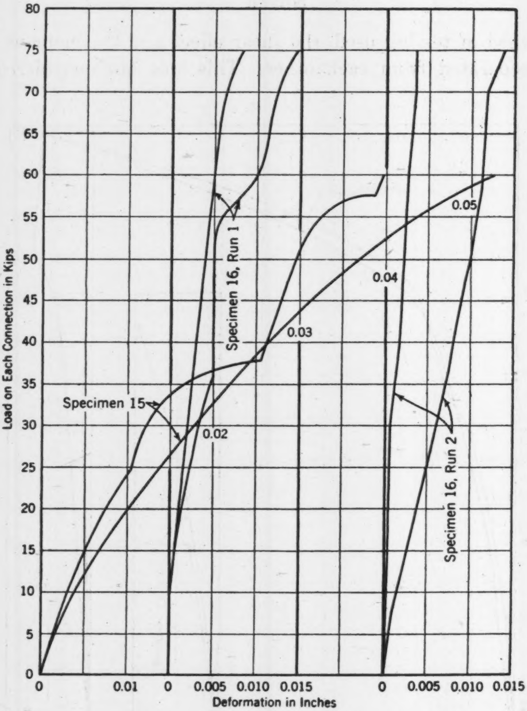

FIG. 25.—DEFORMATION DUE TO SHEAR, SPECIMENS 15 AND 16, SERIES *C*.

In Series *C* the shear dials were clamped to the I-beam as nearly midway between the flanges as possible, while the stem rested on a bracket secured to the central plate. All shear dials registered to 0.0001 in. The readings of these dials had to be corrected for the angular change of the I-beam due to rotation of the connection before the shear curves were plotted. The curves were drawn with the vertical displacement of the connection plotted against the load on the connection. This latter is one-half the load on the specimen. Figs. 24, 25, and 26 give some idea of the capacity of this type of connection to resist shear when not reinforced by clip angles, or by other means. In plotting the shear curves of the second runs of Specimens 14 and 16 (Figs. 24 and 25), deflection under no load was taken as zero and not as the set from the previous run.

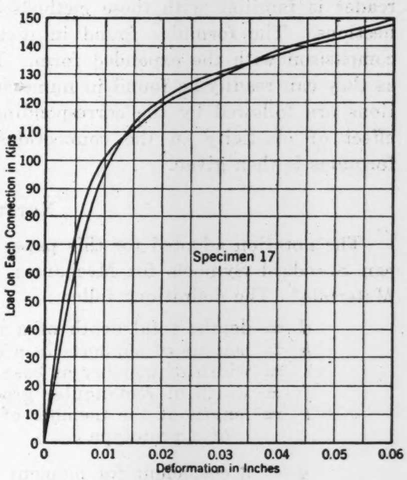

FIG. 26.—DEFORMATION DUE TO SHEAR, SPECIMEN 17.

PART II.—APPLICATION TO FRAMED STRUCTURES

INTRODUCTION

In order to facilitate the incorporation of the effect of the elasticity of the connections in the analysis of framed structures, the principal formulas of the several methods of frame analysis have been expanded to include this as a factor. The methods of Slope Deflection and Moment Distribution have been considered. The Theorem of Three Moments has been rewritten to include elastic connections and the Deformator Method of stress analysis is discussed briefly.

It is to be noted that few of the moment-rotation curves obtained experimentally in Part I approach a straight line even in the lower values. This makes it necessary to assume an arbitrary value for the moment on the connection, or for its angular rotation when substituting in the formulas involving the elasticity of connections. After the moment on this connection is computed it can be compared with the original assumption and the error corrected. Stated in another way, as the curves of Part I have no mathematical equations there seems to be no way of avoiding the trial-and-error method of computing when other than approximate results are desired.

For the purpose of yielding a first approximation and also to provide a comparison of the elastic properties of the several connections, the case of a beam uniformly loaded and connected at each end to a rigid column for each of the connections listed, has been analyzed.

In expanding the formulas of the several methods it is assumed that the reader is familiar with these methods as applied to frames with rigid connections. The formulas found in texts on the subject are first given for comparison with the expanded form. Their derivation and use are omitted as they can readily be found in numerous books on the subject. These equations are followed by the corresponding formulas, expanded to include the effect of elasticity in the connections. The derivation of the expanded formulas is then given.

NOTATION

The notation adopted for this paper conforms essentially with the American Standard Symbols for Mechanics, Structural Engineering, and Testing Materials.[5] The definitions follow:

d = depth; total depth of a member.
h = heights of supports in a continuous beam.
i = width of member at base of groove in model.
j = width of rectangular groove in model.
l = length of the member of a model, corresponding to length, L, of a prototype.
q = a coefficient for moment in Table 3 $= -\dfrac{M}{w\,L^2}$.
t = thickness of model sheet.
u = a coefficient for moment in Table 3 $= -\dfrac{M}{w\,L^2}$.
w = unit uniformly distributed load, or load per unit length on a uniformly loaded member.
x = variable distances measured parallel to X-axis; $\bar{x}$ = distance from the left support to the center of gravity of Area A; $\bar{x}_1$ = distance from right support to center of gravity of Area A.
y = deflection; also, variable distances measured parallel to the Y-axis.
A = area of the moment curve due to transverse loads, the member being considered as a simple beam.
E = modulus of elasticity; E_c = modulus of elasticity of model material.
I = rectangular moment of inertia of a cross-section of a member.
K = stiffness factor.
L = length; nominal length of a member (distance from center to center of connections); L_1 and L_2 = transformed lengths of a member as defined in Equations (18) and (19); L_a = nominal length of the member in Span a; and L_{BC} = the length of the member in Span $B\,C$, transformed by the connection at Point B.
M = moment; M_c = moment at end of a loaded beam, with rigid connections and with length, L.
S = sections modulus of a cross-section of a member.

---

[5] A. S. A.—Z 10a—1932.

Z = a coefficient of M such that $MZ = \theta_M$ = angle of rotation of the connection due to moment, M, values of Z being taken from Figs. 12 to 23.

α = ratio of the deflection of one end with respect to the other end, to the length of the member (Fig. 27).

$\beta = \theta_A - \alpha$ = slope at left end of a beam.

$\gamma = \theta_B - \alpha$ = slope at right end of a beam.

Δ = displacement; the displacement of the central support from a line joining the two end supports in a continuous beam.

θ = an angular distance; change in slope of the end tangent to the elastic curve; the angle of rotation of a connection; $\theta_M = MZ$ = angle of rotation of the connection due to moment, M, taken from Figs. 12 to 23.

σ = scale ratio of a model.

τ = ratio of characteristics of a model and its prototype; τ_r = ratio between two expressions for rigidity in model and prototype; τ_e = ratio between two expressions for elasticity in model and prototype.

SLOPE DEFLECTION METHOD

The slope deflection method consists of the proper application of certain formulas to the analysis of rigid frames. When the connections are rigid the three fundamental formulas and their use are given in texts and treatises on the subject. The formulas for any beam, AB, are:

$$M_A = 2\,E\,\frac{I}{L}\,(2\,\theta_A + \theta_B - 3\,\alpha) - M_{cA} \quad \ldots\ldots\ldots\ldots\ldots (1)$$

and,

$$M_B = 2\,E\,\frac{I}{L}\,(2\,\theta_B + \theta_A - 3\,\alpha) + M_{cB} \quad \ldots\ldots\ldots\ldots\ldots (2)$$

and when the right end is hinged:

$$M_A = 3\,E\,\frac{I}{L}\,(\theta_A - \alpha) + \frac{3\,A\,\overline{x_1}}{L^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

When the end connections are not rigid and allowance is made for the elastic properties of the connections, Equations (1) and (2) become:

$$M_A = 6\,E\,I\;\frac{2\,L_{2B}\,(\theta_A - \alpha) + L\,(\theta_B - \alpha)}{4\,L_{2A}\,L_{2B} - L^2} - M_{cA} \quad \ldots\ldots\ldots (4)$$

and,

$$M_B = 6\,E\,I\;\frac{2\,L_{2A}\,(\theta_B - \alpha) + L\,(\theta_A - \alpha)}{4\,L_{2A}\,L_{2B} - L^2} + M_{cB} \quad \ldots\ldots\ldots (5)$$

in which, $L_2 = L + 3\,E\,I\,Z$ and Z is a coefficient of M, such that $M\,Z = \theta_M$ = angle of rotation of the connection due to the moment, M. The signs of M_A, M_B, θ_A, θ_B, and α in Equations (1) to (5) are positive as indicated in Fig. 27; that is, the moment is positive when it tends to turn the member in a counter-clockwise direction. Angular changes are positive when they move in this same direction.

M_{cA} and M_{cB} are the end moments on the beam (considered fixed at the ends by rigid connections in Equations (1), (2), and (3), and by elastic

connections in Equations (4) and (5)), due to external loads on the beam. For the rigid connections these values are:

$$M_{cA} = -\frac{2A}{L^2}(2L - 3\bar{x}) \quad \dots\dots\dots\dots\dots\dots (6)$$

and,

$$M_{cB} = -\frac{2A}{L^2}(2L - 3\bar{x}_1) \quad \dots\dots\dots\dots\dots\dots (7)$$

and, for the beam with elastic connections, they are:

$$M_{cA} = -\frac{6A}{L} \times \frac{2L_{2B}\bar{x}_1 - L\bar{x}}{4L_{2A}L_{2B} - L^2} \quad \dots\dots\dots\dots\dots (8)$$

and,

$$M_{cB} = -\frac{6A}{L} \times \frac{2L_{2A}\bar{x} - L\bar{x}_1}{4L_{2B}L_{2A} - L^2} \quad \dots\dots\dots\dots\dots (9)$$

As M_{cA} and M_{cB} are the moments at the ends of a beam, their sign follows the convention of the beam theory (positive moment produces compression on the upper side of the beam) and not the convention designated by Fig. 27. By following the signs given in Equations (1) to (5), however, no confusion should arise from this source.

By replacing L_2 by L in Equations (4), (5), (8), and (9), Equations (1), (2), (6), and (7) result.

By making L_{2B} equal to infinity (a hinged connection at B) and L_{2A} equal to zero (a rigid connection at A) in Equations (4) and (8), Equation (3) results.

In applying the slope deflection method to a rigid frame with riveted connections the only change from customary procedure is the use of Equations (4), (5), (8), and (9) instead of Equations (1), (2), (3), (6), and (7). After the values of L_2 are ascertained little more work is required in the application of the longer formulas.

Derivation of Formulas.—To derive the necessary formulas consider the member shown in Fig. 27. This beam is acted upon by loads (shown as a single load, producing a moment curve, *abc*), and the end moments, M_A and M_B. All of them acting simultaneously, produce the moment curve of Fig. 27(*b*). It is to be noted that although M_A is positive, it produces a negative moment on the moment curve. The $\frac{M}{EI}$-curve is shown in Fig. 27(*c*) and is obtained by dividing the ordinates of the curve of Fig. 27(*b*) by the corresponding *EI*-value of the beam. The area of this curve denotes an angular change and is dimensionless. The differential area, $\frac{M}{EI}\,dx$, is a differential angular change in the beam at the point where this area is taken. The effect of the elastic connections is to cause a change in the slope of the beam at the point where the connection is located. As stated previously, this may be taken as $M\ Z$ and, like the area of the curve, is a dimensionless expression. It is represented on the curve, Fig. 27(*c*), by the heavy lines labeled $M_A Z_A$ and $M_B Z_B$.

From Fig. 27(*e*) it can be seen that the deflection of Point B from a tangent to the curve at Point A is $(\theta_A - \alpha)\ L$. It must be remembered that such angles as θ and α are very small and not as shown in the diagram, hence the tangent of the angle may be taken as equal to the angle. This same deflection can also be computed by taking the first moment of the $\frac{M}{EI}$-curve about Point B and adding thereto the angular change at the connection, A, multiplied by the length, L. Computing the deflection of Point B from the tangent at Point A by both methods and equating them:

$$-(\theta_A - \alpha)\,L = -\frac{M_A L}{2\,EI} \times \frac{2\,L}{3} + \frac{M_B L}{2\,EI} \times \frac{L}{3} - M_A Z_A L + \frac{A\,\overline{x_1}}{EI}$$

which may be simplified into:

$$(\theta_A - \alpha)\,L - \frac{2\,M_A L^2}{6\,EI} - M_A Z_A L + M_B \frac{L^2}{6\,EI} + \frac{A\,\overline{x_1}}{EI} = 0$$

Substituting the value of $L_2 = L + 3\ E\ I\ Z_A$:

$$(\theta_A - \alpha)\,L - \frac{2\,M_A L L_{2A}}{6\,EI} + \frac{M_B L^2}{6\,EI} + \frac{A\,\overline{x_1}}{EI} = 0 \quad \ldots\ldots(10)$$

Multiplying by 6 $E\,I$ and dividing by L, Equation (10) becomes:

$$2\,L_{2A}\,M_A - L\,M_B = 6\,E\,I\,(\theta_A - \alpha) + \frac{6\,A\,\overline{x_1}}{L} \quad \text{.........(11)}$$

Taking the deflection of Point A from the tangent at Point B in a similar manner:

$$2\,L_{2B}\,M_B - L\,M_A = 6\,E\,I\,(\theta_B - \alpha) - \frac{6\,A\,\overline{x}}{L} \quad \text{.........(12)}$$

The values of M_A and M_B can be obtained by solving Equations (11) and (12) simultaneously, obtaining:

$$M_A = 6\,E\,I\,\frac{2\,L_{2B}\,(\theta_A - \alpha) + L\,(\theta_B - \alpha)}{4\,L_{2A}\,L_{2B} - L^2} + \frac{6\,A}{L} \times \frac{2\,L_{2B}\,\overline{x_1} - L\,\overline{x}}{4\,L_{2A}\,L_{2B} - L^2} \quad \text{.(13)}$$

and,

$$M_B = 6\,E\,I\,\frac{2\,L_{2A}\,(\theta_B - \alpha) + L\,(\theta_A - \alpha)}{4\,L_{2B}\,L_{2A} - L^2} - \frac{6\,A}{L} \times \frac{2\,L_{2A}\,\overline{x} - L\,\overline{x_1}}{4\,L_{2B}\,L_{2A} - L^2} \quad \text{..(14)}$$

Equations (13) and (14) are identical with Equations (4) and (5) when the Values of M_{cA} and M_{cB} are substituted from Equations (8) and (9).

A second method of obtaining Equations (11) and (12) is by the conjugate beam method. The slope at the ends of a beam are the same as the reactions of a conjugate beam of the same length carrying the $\frac{M}{E\,I}$-curve as a load. Let these reactions be denoted by β and γ. Computing these values by taking moments first about Point B and then about Point A in Fig. 27(c) and noting from Fig. 27(d) that $\beta = \theta_A - \alpha$, and $\gamma = \theta_B - \alpha$, Equations (11) and (12) are obtained at once.

FIG. 29.

Evaluation of L_2 and L_1.—The expression, L_2, is used instead of $L + 3\,E\,I\,Z$ for the purpose of simplifying the formulas. As 3 $E\,I\,Z$ is in units of length it may be visualized as the change in the length of the member due to the elasticity of the connections and L_2 may be visualized as the transformed length of the member.

In order to obtain a more accurate expression for L_2, that takes into account the stiffening effect of the connections of the types shown in Fig. 28(*a*), assume that the member is acted upon by a moment, M_A, at Point *A*. The moment at End *B* may be considered as zero. The moment on the I-beam is zero at the end where the instruments measuring Z were attached. The customary assumption is made that the shear (horizontal) is distributed equally between rivets and that the moment curve is straight in the connections instead of stepped as shown in Fig. 28(*b*). The angular change due to this stepped moment in the I-beam is, then, $M_A\, Z_{1A} = M_A \frac{b}{L} \times \frac{c}{2\,E I}$, approximately, and the total deflection of Point *B* from a tangent to the curve at Point *A* due to a moment, M_A, may be written as:

$$M_A\, Z_A\, (L - a) + M_A\, Z_{1A} \left(b + \frac{c}{3}\right) + M_A \frac{b}{L} \times \frac{b^2}{3\,E I} \; \ldots\ldots \; (15)$$

which was assumed as $\frac{2\,M_A\, L\, L_2}{6\,E I}$ in deriving Equation (10).

Placing these two expressions equal will give a corrected definition for L_2:

$$L\, L_2 = 3\,E\,I\,Z_A\,(L - a) + 3\,E\,I\left(b + \frac{c}{3}\right) Z_1 + \frac{b^3}{L} \; \ldots\ldots \; (16)$$

Dividing by L and substituting the value of Z_1:

$$L_2 = 3\,E\,I\,Z\left(1 - \frac{a}{L}\right) + \frac{3}{2}\left(b + \frac{c}{3}\right)\frac{b\,c}{L^2} + \frac{(L - e)^3}{L^2} = L + 3\,E\,I\,Z\left(1 - \frac{a}{L}\right)$$

$$- 3\,e\left(1 - \frac{e}{L}\right) + \frac{b\,c}{2\,L^2}\,(3\,b + c) - \frac{e^3}{L^2} \; \ldots\ldots\ldots\ldots \; (17)$$

The last term is small except for short beams. When it is neglected the expression for L_2 becomes:

$$L_2 = L - 3\,e\left(1 - \frac{e}{L}\right) + \frac{b\,c}{2\,L^2}\,(3\,b + c) + 3\,E\,I\,Z\left(1 - \frac{a}{L}\right) \ldots (18)$$

In the case of the beam partly restrained at the end, the expression, $2\,L_2 + L$, occurs in the equations. By substituting $3\,L_1$ for $2\,L_2 + L$, these equations can be simplified. With this definition of L_1, Equation (15) becomes:

$$L_1 = L - 2\,e\left(1 - \frac{e}{L}\right) + \frac{b\,c}{L^2}\left(b + \frac{c}{3}\right) + 2\,E\,I\,Z\left(1 - \frac{a}{L}\right) \ldots (19)$$

Dropping the term, $\frac{a}{L}$, would, to some extent, allow for the deformation due to shear in the connection which has been neglected in deriving these formulas. Dropping this term and the others that may be negligible:

$$L_2 = L + 3\,E\,I\,Z - 3\,e \; \ldots\ldots\ldots\ldots\ldots\ldots\ldots \; (20)$$

and,

$$L_1 = L + 2\,E\,I\,Z - 2\,e \; \ldots\ldots\ldots\ldots\ldots\ldots\ldots \; (21)$$

The Beam Partly Restrained at the Ends.—Probably the case that occurs the greatest number of times in steel design is that of the beam partly restrained at the ends by the connections. It is customary in designing such a beam to consider the connections as hinged. If, however, the ends are partly restrained by these connections the moment curve is as shown in Fig. 29(*b*), and a material saving can often be made. To find the value of the negative moment at the ends of the beam, Equations (8) and (9) are used in conjunction with Equations (4) and (5).

The beam with fixed ends is only a special case of the beam of Fig. 27, in which, θ_A, θ_B, and α are all zero, and therefore the first terms of Equations (4) and (5) disappear.

The Partly Restrained Beam Under Uniform Load.—Of especial interest is the beam fixed at the ends by an elastic connection and loaded uniformly throughout its length. To find the value of the negative moment, the following values are substituted in Equation (8) or in Equation (9):

$$A = \frac{1}{8} w L^2 \times \frac{2}{3} L = \frac{1}{12} w L^3;\ L_{2A} = L_{2B} = L_2;\ \overline{x} = \overline{x}_1 = \frac{L}{2}$$

from which,

$$M_{cA} = M_{cB} = -\frac{6\,w L^3}{12\,L} \times \frac{(2\,L_{2B} - L)\frac{L}{2}}{4\,L_2^2 - L^2} = \frac{-\,w L^3}{4\,(2\,L_2 + L)} = -\frac{w L^3}{12\,L_1} \ldots (22)$$

in which, the value of L_1 is given in Equation (19).

The moment at the center of the span is:

$$\frac{1}{8}\,w L^2 + M_{cA} = \frac{1}{8}\,w L^2 - \frac{w L^3}{12\,L_1} = \frac{1}{8} w L^2 \left(1 - \frac{2\,L}{3\,L_1}\right) \ldots\ldots (23)$$

If the moments at the ends and center of this span are assumed equal to $u\,w\,L^2$ and $q\,w\,L^2$, thus defining u and q:

$$u = \frac{-\,L}{12\,L_1} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

and,

$$q = \frac{1}{8}\left(1 - \frac{2\,L}{3\,L_1}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

If the moment at the center of the span is not numerically greater than that at the end, the I-beam at the connection governs the limit of the load. It is recognized that the evaluation of the unit stress in the I-beam at the connection is not as simple as herein implied because, doubtless, the stresses in the connection govern, rather than those in the I-beam, near the connection.

The importance of the several terms of Equation (19) can best be demonstrated by an example. For this purpose a beam of a length equal to twelve times its nominal depth has been chosen. The load is assumed to be of sufficient value to give a fiber stress of 18 000 lb per sq in. Table 3 gives

* $M_e = 18\ 000\ S$, in inch-pounds.

the results of the computations for the several connections tested in Part I. In computing the first fifteen connections in Table 3 the values of M_u were assumed, the values of $M\ Z$ were read from the curve, after which L_1 was computed. From the formula, $M_u = M_q \left[\dfrac{-2L}{3L_1 - 2L}\right]$ (obtained from Equations (24) and (25)), the assumed values were checked. In these cases the values of M_q were taken as 18 000 S, in which, S is the section modulus of the beam. In the case of Specimens 13, 14, and 17, the stress at the end of the beam rather than that at the center was the determining factor. The moment, M_q, was computed from the reciprocal formula, $M_q = M_u\left(1 - \dfrac{3L_1}{2L}\right)$. From Fig. 29 it is seen that $-M_u + M_q = \frac{1}{8} w L^2$, the formula customarily used in solving this problem. The increase of strength obtained by considering the connection as elastic over the hinged connection is given by the expression, $\dfrac{-M_u + M_q}{18\,000\,S}$. This is given in Column (19), Table 3.

THEOREM OF THREE MOMENTS

The theorem of three moments may be written (see Fig. 30):

$$\frac{L_a}{I_a} M_A + 2\left(\frac{L_a}{I_a} + \frac{L_b}{I_b}\right) M_B + \frac{L_b}{I_b} M_C + \frac{6A_a\overline{x_a}}{L_a I_a} + \frac{6A_b\overline{x_{1b}}}{L_b I_b}$$
$$= 6E\Delta\left(\frac{1}{L_a} + \frac{1}{L_b}\right) \text{ .... } (26)$$

Equation (26) is found in many forms all of which can be transformed into the one here given or can be derived as special cases of it. If the

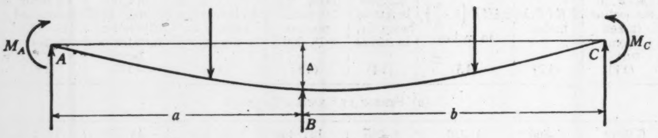

FIG. 30.

elasticity of the connections is taken into consideration the theorem changes only in its second term which becomes:

$$\frac{L_a}{I_a} M_A + 2\left(\frac{L_{BA}}{I_a} + \frac{L_{BC}}{I_b}\right) M_B + \frac{L_b}{I_b} M_C + \frac{6A_a\overline{x_a}}{L_a I_a} + \frac{6A_b\overline{x_{1b}}}{L_b I_b}$$
$$= 6E\Delta\left(\frac{1}{L_a} + \frac{1}{L_b}\right) \text{ .... } (27)$$

In Equations (26) and (27) (and in Equation (33) which follows), as well as in their derivation, the signs of the moments are assumed positive when they produce compression in the top fibers of the beam rather than by the convention used in the "Slope Deflection Method." This is done to be consistent with current practice in the use of the Theorem of Three Moments. This theorem (Equation (26) and Equation (27)) may be considered as a special case readily derived from the slope deflection equations. The theorem expresses only the relationship between the loads on a continuous beam on three supports, the elastic properties of the beam, and the moment at the deflection of the central support. The end moments are considered as loads.

To derive Equation (27), it is only necessary to note that the slope of Span *AB* at Point *B*, is the same as the slope of Span *BC* at the same point.

Span *AB* may be considered as hinged at the left end and elastically connected at the right, while Span *BC* is hinged at the right and elastically connected at the left end. For a beam with a hinge at the left end, Equation (14) becomes:

$$M_B = \frac{3\,E\,I\,(\theta_B - \alpha)}{L_{2B}} - \frac{3\,A\,\overline{x}}{L\,L_{2B}} \quad \text{..............} (28)$$

when L_{2A} becomes infinite, while for a beam with a hinge at the right end, Equation (13) becomes (after changing the sign of M_A):

$$-\,M_A = \frac{3\,E\,I\,(\theta_A - \alpha)}{L_{2A}} + \frac{3\,A\,\overline{x}_1}{L\,L_{2A}} \quad \text{..............} (29)$$

For Span *A B* substitute the following in Equation (28): $M_{BA} = M_{BC} = M_B$; $A\,\overline{x} = A_a\,\overline{x}_a + \dfrac{M_A\,L^2_a}{6}$; and $\alpha = -\dfrac{\Delta}{L_a}$. Then,

$$L_{BA}\,M_B = 3\,E\,I_a\left(\theta_B + \frac{\Delta}{L_a}\right) - \frac{3\,A_a\,\overline{x_a}}{L_a} - \frac{M_A\,L_a}{2}$$

Similarly, substitute in Equation (29) for Span *BC*, $M_A = M_{BC}$; $A\overline{x}_1 = A_b\,\overline{x}_{1b} + \dfrac{M_C\,L^2_b}{6}$, and $\alpha = \dfrac{\Delta}{L_b}$, obtaining:

$$-\,L_{BC}\,M_B = 3\,E\,I_b\left(\theta_A - \frac{\Delta}{L_b}\right) + \frac{3\,A_b\,\overline{x}_{1b}}{L_b} + \frac{M_C\,L_b}{2} \quad \text{......} (30)$$

Eliminating θ_A and θ_B between these two equations by taking advantage of the fact that they are equal:

$$3\,E\left(\theta_B + \frac{\Delta}{L_a}\right) = \frac{L_{BA}}{I_a}\,M_B + \frac{L_a}{2\,I_a}\,M_A + \frac{3\,A_a\,\overline{x_a}}{L_a\,I_a} \quad \text{.........} (31)$$

and,

$$3\,E\left(\theta_A - \frac{\Delta}{L_b}\right) = -\,\frac{L_{BC}}{I_a}\,M_B - \frac{L_b}{2\,I_b}\,M_C - \frac{3\,A_b\,\overline{x}_{1b}}{L_b\,I_b} \quad \text{........} (32)$$

Subtracting Equations (31) and (32), Equation (27) follows.

The term, $\Delta\left(\dfrac{1}{L_a} + \dfrac{1}{L_b}\right)$, may be replaced by $\dfrac{h_A - h_B}{L_a} - \dfrac{h_B - h_C}{L_b}$. This comes from the geometry of the figure, in which, h_A, h_B, and h_C are the heights of the several supports, the assumption being made that they are in line when the beam is not strained.

For the special case in which there is no settlement of supports and the beam carries a uniform load, Equation (27) becomes:

$$\frac{L_a}{I_a} M_A + 2\left(\frac{L_{BA}}{I_a} + \frac{L_{BC}}{I_b}\right) M_B + \frac{L_b}{I_b} M_C + \frac{w\,L^3_a}{4\,I_a} + \frac{w\,L^3_b}{4\,I_b} = 0 \quad \ldots (33)$$

MOMENT DISTRIBUTION METHOD

In the moment distribution method of analyzing rigid frames, three groups of formulas are required: (1) The moment induced at either end of a beam by loads when the beam is considered as fixed-ended; (2) the moment induced at one end of a beam by a moment imposed at the other; and (3) the rigidity of the beam with respect to a moment at the end.

Equations (6) and (7), and the last term of Equation (3), fulfill the requirements for the first group when no correction is made for the yielding of the connections; Equations (8) and (9) fulfill the requirements when this factor is taken into consideration.

In the second group of formulas, the carry-over factor is 0.500 in the case of rigid connections. In the case of elastic connections this factor can be obtained from Equations (13) and (14). Let the beam of Fig. 27(*a*) be the one under consideration; let $\theta_B = 0$; $A = 0$; and $\alpha = 0$; then:

$$M_A = 6\,E\,I\,\frac{2\,L_{2B}\,\theta_A}{4\,L_{2A}\,L_{2B} - L^2} \quad \ldots\ldots\ldots\ldots (34)$$

and,

$$M_B = 6\,E\,I\,\frac{L_{2A}\,\theta_A}{4\,L_{2B}\,L_{2A} - L^2} \quad \ldots\ldots\ldots\ldots (35)$$

Eliminating θ_A between Equations (34) and (35):

$$M_B = M_A\,\frac{L}{2\,L_{2B}} \quad \ldots\ldots\ldots\ldots (36)$$

The carry-over factor then is $\frac{L}{2\,L_{2B}}$ which reduces to 0.500 when L_{2B} is equal to L.

In order to find the rigidity of the beam with respect to the moment at End A or End B (which is given by the formulas, $\theta_A = \frac{M_A\,L}{4\,E\,I}$ and $\theta_B = \frac{M_B\,L}{4\,E\,I}$, for rigid connections), it is only necessary to solve Equation (34) for θ, thus,

$$\theta_A = M_A\,\frac{4\,L_{2A}\,L_{2B} - L^2}{12\,L_{2B}\,E\,I} = M_A\left(\frac{L_{2A}}{3\,E\,I} - \frac{L^2}{12\,L_{2B}\,E\,I}\right)$$

$$= \frac{M_A}{3\,E\,I}\left(L_{2A} - \frac{L^2}{4\,L_{2B}}\right) \quad \ldots\ldots\ldots\ldots (37)$$

and,

$$\theta_B = \frac{M_B}{3\ E\ I}\left(L_{2B} - \frac{L^2}{4\ L_{2A}}\right) \ldots\ldots\ldots\ldots\ldots\ldots (38)$$

Equations (37) and (38) are the formulas from which the stiffness of the beam may be determined when computing the unbalanced moment distribution about a joint. If $L_2 = L$ in Equations (37) and (38) the usual formulas for both ends rigidly connected obtain. If End A is hinged and End B is rigid, Equation (38) reduces to $\theta_B = \frac{M_B L}{3\ E\ I}$, as $L_{2B} = L$ and L_{2A} = infinity.

Examples.—The changes in the moment distribution method due to elastic connections can best be illustrated by comparing the solution of a problem in which all connections are rigid with that of one in which some of the connections are taken as elastic.

Consider the beam of Fig. 31 supporting a uniform load, w, of 100 lb per ft. The connections at Points A and D are hinged and the beam, at Point C, is continuous. The beam will first be considered as continuous at Point B, and, later, the case of elastic connections at Point B will be solved. These two problems are analyzed in a parallel manner so that a comparison can readily be made between them.

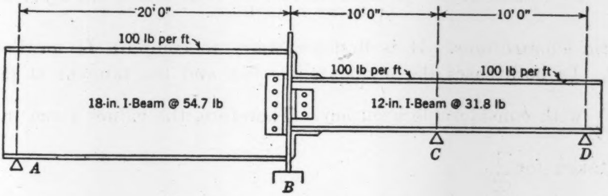

FIG. 31.—A CONTINUOUS BEAM.

Rigid Connections.—The fixed-end moments, M_c, for this case (Fig. 31) are:

$$M_{BA} = -\frac{3\ A\ \overline{x}}{L^2} = -\frac{3 \times 48 \times 10^5}{240} = -60 \times 10^3$$

$$M_{BC} = M_{CB} = -\frac{2\ A\ \overline{x}}{L^2} = -\frac{2 \times 6 \times 10^5}{120} = -10 \times 10^3$$

and,

$$M_{CD} = -\frac{3\ A\ \overline{x}}{L^2} = -\frac{3 \times 6 \times 10^5}{120} = -15 \times 10^3$$

The carry-over factor is 0.5000 for both ends of Beam BC. The stiffness factors for the several beams are evaluated as follows:

$$K_{BA}\ E\,\theta = \frac{3I}{L}\ E\,\theta = \frac{(3)\ (795.5)}{240}\ E\,\theta = 9.93\ E\,\theta$$

$$K_{CB}\ E\,\theta = K_{BC}\ E\,\theta = \frac{4I}{L}\ E\,\theta = \frac{(4)\ (215.8)}{120}\ E\,\theta = 7.2\ E\,\theta$$

and,

$$K_{CD}\,E\,\theta = \frac{3\,I}{L}\,E\,\theta = \frac{(3)\ (215.8)}{120}\,E\,\theta = 5.4\,E\,\theta$$

These values are used in the computations shown in Fig. 32.

FIG. 32.—COMPUTATIONS FOR BEAM IN FIG. 31, CONSIDERING THE CONNECTION AT POINT B AS RIGID.

Elastic Connections.—It is first necessary to compute L_2 for Beams BA and BC. In both cases the moments are low and the tangent at the origin gives $\frac{M}{M\,Z}$ with considerable accuracy. Therefore, the values given in Table 2 will be taken for $\frac{1}{Z}$.

From Equation (18):

$$L_{2BA} = 240 - 7.5 + \frac{(3)\ (3)\ (10)^7\ (795.5)}{(10)^8\ (2.9)} = 232.5 + 246.5 = 479$$

$$L_{2BC} = 120 - 14.5 + 3.5 + \frac{(3)\ (3)\ (10)^7\ (215.8)}{(10)^8\ (4.2)} = 109 + 46 = 155$$

$$A\ \overline{x}_{AB} = \frac{w\,L^3}{24} = \frac{(100)\ (20)\ (240)^3}{24} = (1\,152)\ (10)^6$$

$$A\ \overline{x}_{BC} = A\ \overline{x}_{CB} = \frac{(100)\ (10)\ (120)^3}{24} = (72)\ (10)^6$$

and the fixed moments, M_c,

$$M_{BA} = \frac{-\,3\,A\,\overline{x}}{L\,L_{2BA}} = \frac{-\,(3)\ (1\,152)\ (10)^6}{(240)\ (479)} = -\ 29\,900$$

$$M_{BC} = \frac{-\,6\,A\,\overline{x}}{L\,(4\,L_2 - L)} = \frac{-\,(6)\ (72)\ (10)^6}{(120)\ (620 - 120)} = -\ 7\,200$$

$$M_{CB} = \frac{-\,6\,A\,\overline{x}\ (2\,L_2 - L)}{L^2\,(4\,L_2 - L)} = \frac{-\,(6)\ (72)\ (10)^6\ (190)}{(120)^2\ (500)} = -\ 11\,400$$

$$M_{CD} = \frac{-\,3\,A\,\overline{x}}{L^2} = -\ 15\,000$$

The carry-over factor is 0.50 for the right end of Beam *BC*, but for the left end, it is $\dfrac{L}{2\,L_2} = \dfrac{120}{(2)\ (155)} = 0.387.$

The stiffness factors, *K*, for the several beams are:

$$K_{BA}\ E\ \theta_B = \frac{I}{L_1}\ (3\ E\ \theta_B) = \frac{795.5}{479}\ (3\ E\ \theta_B) = (1.66)\ (3\ E\ \theta_B)$$

$$K_{BC}\ E\ \theta_B = \frac{4\ I}{4\ L_2 - L}\ 3\ E\ \theta_B = \frac{4\ (215.8)}{620\ -\ 120} = (1.73)\ (3\ E\ \theta_B)$$

$$K_{CB}\ E\ \theta_C = \frac{4\ L_2\ I}{L\ (4\ L_2 - L)}\ 3\ E\ \theta_C = \frac{(4)\ (155)\ (215.8)}{(120)\ (500)}\ 3\ E\ \theta_B = (2.24)\ (3\ E\ \theta_C)$$

and,

$$K_{CD}\ E\ \theta_C = \frac{I}{L}\ 3\ E\ \theta_C = \frac{215.8}{120}\ 3\ E\ \theta_B = (1.80)\ (3\ E\ \theta_C)$$

Using the foregoing values and computing the moment distribution the same as in Fig. 32, the results, considering the connection at Point *B* as elastic, are shown in Fig. 33. The results may be checked by the theorem of three moments by substituting the proper values in Equation (33), with the result that, $M_B = -\ 17\,800$; and $M_C = -\ 10\,550$.

FIG. 33.—COMPUTATIONS FOR THE BEAM IN FIG. 31, CONSIDERING THE CONNECTION AT POINT *B* AS ELASTIC.

DEFORMETER METHOD

The analysis of a structure by means of the deformeter method requires a model cut from a sheet of celluloid or other elastic material. In designing this model, if deformation depends primarily on bending as it does in building frames, the moment of inertia of the various parts must be proportional to those of the structure. This proportion also applies to the connections. The widths of the various parts of the model, as *d*, are computed so that the cubes of these widths are proportional to the moments of inertia of the corresponding members. The rigidity of each member is proportional to $\frac{EI}{L}$ whereas that of the corresponding member in the model is $\frac{E_c t d^3}{12\, l}$, in which, E_c is the modulus of elasticity of the model material; l is the length of the member; and t is the thickness of the sheet of celluloid. If the ratio between these two expressions for rigidity is τ_r, then, $\tau_r = \frac{E_c t d^3}{12\, l} \div \frac{EI}{L}$; or,

$$\tau_r = \frac{E_c\, t\, d^3\, L}{12\, l\, E\, I} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (39)$$

The same ratio should exist between the elasticity of the connections in the structure and in the model, whence: $\tau_r = \frac{E_c t i^3}{12\ j} \div \frac{1}{Z}$; or,

$$\tau_r = \frac{E_c\, t\, i^3\, Z}{12\, j} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (40)$$

Eliminating τ_r between Equations (39) and (40),

$$\frac{j}{i^3} = \sigma\ \frac{E\, I\, Z}{d^3} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (41)$$

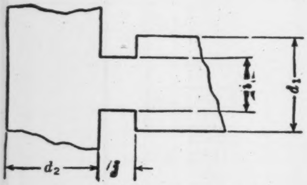

FIG. 34.

In which, σ is the scale ratio of the model; j is the width of a rectangular groove cut in the member at the location of the connection; and i is the width of the member at the base of this groove (see Fig. 34).

SUMMARY AND CONCLUSIONS

The tests described in Part I give the elastic properties of eighteen connections of three distinct types (see Figs. 12 and 26, and Table 2). The tests showed that the connections of Series A can be deformed through angles considerably beyond working conditions without affecting their capacity to resist shear. The connections of Series B possessed this property in a much smaller degree, but are capable of deforming within the working range. The deformations in Series A and B are due to the yielding of the angles rather than to the rivets or main members. The connections shown as Series C are comparatively rigid. Their method of failure can be controlled by detail of design.

Part II indicates the method of analyzing structural frames when consideration is given to the elastic properties of the connections. Expressions for the "transformed length of the member", L_3, and the "transformed length of the beam", L_1, have been developed and incorporated into the formulas for stress analysis by the slope deflection, moment distribution, and deformeter methods, as well as into the theorem of three moments. The saving resulting from utilizing the resistance of the connections in designing a simple beam is indicated in Table 3, where it is shown that the load in some cases may be increased more than 90% by utilizing the support given by the connections.

APPRECIATION

Acknowledgment is freely given to the following for material assistance in the preparation of this paper: G. E. J. Pistor, M. Am. Soc. C. E., through whose interest the steel for these tests was made available and also for many helpful suggestions in planning the tests; Frederick Skene, Dean of the School of Technology, College of the City of New York, for use of their laboratories, equipment, etc., and for his co-operation; A. H. Beyer, O. E. Hovey, and Jonathan Jones, Members, Am. Soc. C. E., for many helpful suggestions during the gathering of the data and the writing of the paper; J. Sanford Peck, Assoc. M. Am. Soc. C. E., for material assistance, co-operation, and many suggestions during the conduct of the tests; A. G. Hayden, M. Am. Soc. C. E., and Mr. C. W. Vanderbilt, of the Kalman Steel Company, for material assistance and helpful suggestions in the preliminary stages of the investigation; Mr. Leo S. Pavelle for his assistance as a photographer; Mr. Arthur Gatterdam for the suggestion of the use of L_s and for a careful review of the derivation of the equations; the McClintic-Marshall Company for furnishing the steel which was fabricated in its Bethlehem (Pa.) shops and delivered to the laboratories; and to the American Institute of Steel Construction for its co-operation in obtaining the steel, and for many suggestions.

DISCUSSION

Ralph E. Goodwin,[6] M. Am. Soc. C. E. (by letter).—Without question, this paper is a genuine contribution to the knowledge of restrained end conditions in beams and rectangular frames and, in a timely manner, Professor Rathbun has saved students of this subject from the sin of pride and the dangers of self-complacency. Just as the profession was becoming acquainted with new means for analyzing rigid frames with some degree of facility Professor Rathbun comes forward with a bitter new "dose" in the form of further complications to problems already so complicated that few engineers other than college professors bother to solve them.

The test results are valuable and the mathematical analysis is clever and cleverly presented. The use of simple beam moments in connection with restrained end conditions in Part II of the paper simplifies the resulting expressions enormously. Further simplification results from the author's use of the symbol, L_2; but he flatters the intelligence of his readers when he assumes that the steps in his derivations and his systems of algebraic signs will be self-evident. In problems of this nature the difficulties with algebraic signs become almost unsurmountable unless the latter are explicitly defined. The tendency of experts is to grow so accustomed to their own particular methods and sign conventions that it does not occur to them that these methods and conventions may not be taken for granted by every one. Since the paper is written for specialists, some engineers who are not expert in this field will have difficulty in following the derivations and in using the resulting equations without further elucidation.

Unfortunately, the author did not make clear in his Figs. 12 to 23 the meaning of the straight diagonal dashed lines and of the straight vertical dashed lines at 0.0089 radian on some of these curves. The straight diagonal dashed lines represent the average slopes of the "set" curves, whereas the straight vertical dashed lines indicate the rotation angle which the ends of a uniformly loaded simple beam make with the horizontal when the beam is deflected one-three-hundred-sixtieth of the span. This value of the rotation angle is thought to be the maximum limit of practical significance. In taking the "set" curves the load was removed and the point taken on these curves as the load was placed back on the specimen.

The general problem of elastic connections is similar in nature to the problem of joint rotation in the slope-deflection method. The yielding of the connection has the same effect upon the end moments of the member as would be produced by joint rotation; but in the equations the two effects must be kept distinct for two reasons: (1) Joint rotation is common to all members meeting at the joint in question, whereas yielding of the connections may not be the same for all members; and (2) yielding of any connection is itself a function of the end moment. In the conventional derivation of the slope-deflection equations for rigid connections, as presented in textbooks, the principle of superposition is utilized in order to add the fixed-end moments to the moments produced by joint rotation and joint translation. This is legitimate since the two effects are assumed to be independent of each other, the angles of joint rotation (θ_A and θ_B) not being functions of the end moments (M_A and M_B); but in the author's work the elastic rotation of a connection is itself a function of the end moment which produces it and, therefore, the ordinary fixed-end moment can not correctly be superposed upon the effects of joint rotation and translation. The author's procedure in respect to this point is correct inasmuch as he derives his slope-deflection equations for elastic connections from first principles and not by superposition. As was to be expected, the restrained-end moments for a beam with elastic connections appear in the expressions for M_A and M_B (Equations (13) and (14)), not the fixed-end moments for rigid connections. It is to be regretted as increasing the chances for error that the author has used the same symbols (M_{CA} and M_{CB}) for the restrained-end moments of a beam with elastic connections as for the fixed-end moments of a beam with rigid connections.

---

[6] Associate Prof., Civ. Eng., School of Technology, Coll. of the City of New York, New York, N. Y.

For moment diagrams the author wisely chooses to utilize the principle that a beam with end moments may be treated as a simple beam carrying the end moments as additional loads, so that his moment diagrams show three separate diagrams superposed, namely: (1) Moment diagram for the transverse loads on a simple beam; (2) moment diagram for end moment on the left, applied as a load on a simple beam; and (3) moment diagram for end moment on the right, applied as a load on a simple beam. This treatment appears to produce maximum simplification of the resulting equations.

In the matter of algebraic signs, always so puzzling, the author is fairly considerate. He offers much specific information in regard to this matter, but the following categorical listing of the rules used for algebraic signs in the paper may be helpful. In the first part of the paper, as far as the "Theorem of Three Moments," the author uses a combination of two sign conventions: The moments of transverse loads follow the beam sign convention; and end couples, joint rotation, joint translation, and yielding of connections follow the slope-deflection sign convention, counter-clockwise rotation being taken as positive. Although it is immaterial for the cases discussed in this paper the writer would like, on general principles, to amend the statement (following Equation (5)) that "the moment is positive when it tends to turn the member in a counter-clockwise direction." A counter-clockwise end moment should always be taken as positive whether acting on the member or on the adjacent joint, but it should be indicated whether the symbols, M_A, M_B, etc., refer to the moment couples acting on the member or to the ones acting on the joint. In the paper the symbols, M_A, M_B, etc., refer to the moment couples acting on the member, so that a positive value of M_A indicates a counter-clockwise couple acting on the member with a corresponding clockwise couple ($-M_A$) acting on the adjacent joint. In plotting moment diagrams when using the direction-of-rotation sign convention the several component diagrams must all be plotted consistently; that is, all must refer to the same face of a section through the member. As regards algebraic signs the author's moment diagrams show the moment couples acting on the left-hand face of a transverse cut through the beam. On this face of the section, the algebraic signs of the moment couples will be the same when determined by the direction-of-rotation sign convention as when determined by the beam sign convention. The foregoing remarks explain the author's statement (under the heading, "Derivation of Formulas") that: "It is to be noted that although M_A is positive, it produces a negative moment on the moment curve." Some may consider it objectionable to combine two different systems of algebraic signs as has been done in the paper, but no difficulty will be experienced in altering the equations by those who desire to make a change in this particular.

In the derivation of the theorem of three moments with elastic connections the beam sign convention is used as more appropriate to this case. In his work the author simplifies his mathematics by treating Joints A and C as hinged and acted upon by the couples, M_A and M_C, considered as loads. He allows for the effect of these couples by treating them as loads on a simple beam and including their effect with that of the transverse loads. In the case of a hinged connection at A, L_{2A} becomes infinite and Equation (14) becomes indeterminate in the form in which it is printed. Equation (28) is obtained by first dividing both numerator and denominator of Equation (14) by L_{2A} and then setting L_{2A} equal to infinity. The equation for $L_{BA}\, M_B$ may be obtained in a different manner by eliminating θ_A from Equations (13) and (14). Similar procedure is followed in obtaining Equations (29) and (30). The assumption is made in the derivation that the differences in elevation between Supports B and A and Supports B and C are the same and that each is equal to Δ. This is equivalent to rotating the pair of spans until Supports A and C are at the same elevation; or, which is the same thing, assuming as a reference axis the line joining Supports A and C. The result is valid when all three supports are at different elevations, and it may be shown that,

$$\Delta\left(\frac{1}{L_a}+\frac{1}{L_b}\right)=\left(\frac{\Delta_a}{L_a}+\frac{\Delta_b}{L_b}\right) \ldots\ldots\ldots\ldots\ldots (42)$$

Perhaps the mathematical part of the paper would appeal to a wider public if the author had been more liberal with explanations, but the subject-matter is of the highest interest, and the purpose of the present discussion is mainly to endorse the paper and to clarify it for the benefit of those who are not expert in this field. Any suggestions made herein are of trivial weight in comparison with the importance of the original work.

HAROLD C. ROWAN,[7] ESQ. (by letter).—The necessity for information as to the rigidity of steel-frame building connections has been widely recognized by structural engineers. In reporting the results of these tests on standard connections the author has provided much useful information.

In the "Introduction" it is stated that no extensive tests have been published on this type of investigation. The writer would like to call attention to the work of the Department of Scientific and Industrial Research of Great Britain.[8] A report published in May, 1934, contains, among other material, the results of a comparatively extensive series of tests conducted at the University of Birmingham, under Professor Cyril Batho. The writer participated in the work.

---

[7] Commonwealth Fund Fellow, Univ. of Illinois, Urbana, Ill.

There appears to be no serious discrepancy between the results obtained by the author for the moment-deformation curves and those obtained at Birmingham. The manner in which flexible connections failed is meaningless because it is impossible in practice for even a small fraction of the deformation involved in failure to occur. The only possibility of failure occurring in such connections is by fatigue. Although it may be true that the strength of the specimens in Series *A* and *B* in shear is not impaired by considerable flexure under moment, their manner of failure alone does not justify that conclusion. Furthermore, the effect of shear on connections of Series *B* is to increase the rigidity. This point may be quite important when considering the rigidity of a dual connection, such as Specimen 11.[9]

The author remarks that the most serious stresses occur in the lower seat angles of Series *B*. It would be noted that the connections were tested upside down as compared with their position in a building, and it is really the top angle which is highly stressed and results in most of the deflection. The same applies to the rivets in the vertical legs of the angles. Specimens 8, 9, 10, 11, and 12 should possibly have been tested the other way up.

The correctness of the author's inference that a seat-angle connection may be stiffened materially by increasing the thickness of the angles was clearly demonstrated, within reasonable limits, in the Birmingham tests.

The type of specimen in which a single plate is used instead of a column section is not representative of the actual conditions obtained in a building. On account of the fact that the column rivets are common to both sides of the specimen, the connections behave as if a rigid plane existed at the mid-section of the plate. When the connection is to a column flange, this is not true, and flexure of the flange will cause lower rigidity. This effect will be largest in the wind-bracing connections, especially where four rows of rivets are used.

The method given by the author for the solution of semi-rigid frames using constants to represent the degree of rigidity of the connections is interesting. It may be mentioned that the British report[8] gives three methods of solution using the same assumptions. A method of interpreting results which does not involve the straight-line assumption, and in which the moment-deformation curve is used to yield immediate results without resorting to trial and error, is also given in the report.[10] By its use the end moments resulting from a uniform load on a beam having the connections under investigation are thus found by drawing a single straight line on the experimental curve and reading the fixing moments directly from the graph. For purposes of interpretation it is best to assume that the beam is attached to rigid columns, but the method is also extended to include the effect of flexure in surrounding members, assuming that their rigidity may be estimated approximately. The effect of a change of load, change of stiffness of a beam due to altering its length or moment of inertia, change of stiffness of surrounding members, or the substitution of some other connection, can be seen immediately. The method has since been extended to cover the cases of unsymmetrical loading and unequal end conditions, or both.

[10] Second Rept. of the Steel Structures Research Comm. of the Dept. of Scientific and Industrial Research, pub. by His Majesty's Stationery Office, London, England, 1934, p. 92.

The rapid design of steel-frame buildings, which is so often necessary, renders it highly improbable that any method involving complete analysis can ever be used in design, and certainly not any complete analysis using trial-and-error methods. Although it is possible in any single case to choose a constant for the moment-deflection relation which will give the same resulting moments as a curve, it may be shown that any such method involves a change in that constant for different lengths of beam, different loads, and different surrounding members. In any method, of course, the accuracy cannot be greater than the reliability of the connections to act according to the assumed or experimental graph, and tests have shown that the curves extend over a fairly wide range.

There are other considerations which make any analysis approximate. The most important is probably the fact that the members and connections of a steel-frame building are generally encased in concrete, and this will probably affect the distribution of the moments and the stresses. Another uncertainty is the capacity of a building to sway sidewise under unsymmetrical loads. Walls, partitions, and floors tend to stiffen the frame, and it is possible that an analysis which neglects side-sway more nearly represents the actual conditions than one which takes account of side-sway.

It may be mentioned that a large number of tests have been made at Birmingham since the writing of the second report mentioned previously.

WALTER SCHOLTZ,[11] JUN. AM. SOC. C. E. (by letter).—In the solution by moment distribution presented in the Part II of this paper, modified slope deflection equations were used to obtain expressions for fixed-end moments, distributed moments, and carry-over factors. The labor of solving these somewhat complicated expressions could be greatly simplified. For example, referring to Fig. 31, consider the elastic connection as an additional, or phantom, member in the frame. For the connection in this example the stiffnesses given for each side are: Left side, $\frac{1}{Z_L} = 2.9 \times 10^8$; and, right side, $\frac{1}{Z_R} = 4.2 \times 10^8$.

For both acting together, $\frac{1}{Z} = \frac{1}{Z_L + Z_R} = \frac{1}{\frac{1}{2.9 \times 10^8} + \frac{1}{4.2 \times 10^8}} = 1.69 \times 10^8$,

in which $\frac{1}{Z}$ is the absolute stiffness, $\frac{M}{\theta}$, for the connection as a member. Its carry-over factor obviously is -1. The analysis now can be performed by ordinary moment distribution, the only precaution to be observed being that of utilizing the absolute stiffness for all members so that the correct relationship to $\frac{M}{\theta}$ for the connection is established. The ordinary fixed-end moments and the carry-over factor of $\frac{1}{2}$ are used.

FIG. 35.

In the solution shown in Fig. 35 the writer has neglected the reduction of the moment at the ends of members due to transfer of shear to the connection at each row of rivets; but the effect of this factor is clearly of small magnitude. The results obtained are identical with those that would be obtained by using $L_s = L + 3\ E\ I\ Z$ in the equations given by Professor Rathbun. Instead of the stiffness factor, K, in Fig. 32, the writer suggests the factor of absolute stiffness, KE, or $\frac{M}{\theta}$. For Span B_1A (Fig. 35, Line 3) $\frac{M}{\theta} = 9.93 \times 3 \times 10^7 = 2.98 \times 10^8$; for Span B_2C, $\frac{M}{\theta} = 7.2 \times 3 \times 10^7 = 2.16 \times 10^8$; and, for Span CD, $\frac{M}{\theta} = 5.4 \times 3 \times 10^7 = 1.62 \times 10^8$. (Note that, for the opposite end fixed, $KE = \frac{4\ I}{L}$ and for the opposite end free, $KE = \frac{3\ I}{L}$). The physical picture on which Fig. 35 is based will be visualized easily by any one familiar with the Cross method, and it permits a simple application in design calculations of the valuable data reported in this paper.

It should be noted that the loading used in this example is only a fraction of the allowable load for these beams. Inasmuch as the slopes of the rotation-moment curves for all the connections decrease materially as the load increases, it follows that for design loadings the connection stiffnesses would be materially less than those used in Fig. 35, which were found by taking the slope of the tangent to the rotation-moment curve at the origin.

J. F. BAKER,[12] ASSOC. M. AM. SOC. C. E. (by letter).—A better understanding of the behavior of steel work connections is essential if the design of steel frames is to be put on a more rational basis and full economy of material obtained. This understanding will follow only from a careful study of such tests as those conducted by Professor Rathbun. It is unfortunate, however, since the behavior of connections is so complex and the field to be covered is so wide, that Professor Rathbun was unaware of the work that has been done in Great Britain since 1930 for the Steel Structures Research Committee of the Department of Scientific and Industrial Research, which was appointed in 1929 on representations from the steel industry backed by an offer of support from the British Steelworks Association. As mentioned in the Committee's First Report, published in 1931, a series of laboratory experiments on beam-to-stanchion connections was undertaken. A detailed report of certain of these tests (which were conducted by Professor Cyril Batho, of Birmingham University, on a series of connections, including all the types dealt with by Professor Rathbun) is given in the Second Report of the Committee, published in 1934.[18] It would be out of place to give a summary of that work here, but it should be studied by all interested in steel design. Characteristics of the connections were given by curves similar to those in the paper under discussion.

---

[12] Prof. of Civ. Eng., Univ. of Bristol, Bristol, England; Technical Officer, Steel Structures Research Committee, London, England.

Professor Rathbun's analysis of framed structures is clearly presented, although certain of the assumptions made in introducing Equations (15) to (21), to obtain a more accurate expression for L_2, are of doubtful value. In the First Report of the Steel Structures Research Committee already mentioned, a general equation was given applicable to frames with semi-rigid connections, to which Professor Rathbun's Equations (4), (5), (8), and (9) will be found to lead. The method of attack in stress analysis is largely a matter of taste, but it is interesting to compare this work. The derivation of this general equation is given in the Second Report, together with expressions for the factors necessary for the application of the moment distribution method. These expressions will be found to agree with Professor Rathbun's factors in the particular case of the continuous beam (see the heading, "Moment Distribution Method"). It must be emphasized that in applying this method to a frame with semi-rigid connections it is essential to take into account the widths of the stanchions if serious errors are not to be made.[18] These methods of analysis are based on the assumption that the relation between moment transmitted by a connection and the relative rotation of the members joined, is linear. This is not true of actual connections and, therefore, in applying the methods an estimate, which may need subsequent correction, must first be made of the moment transmitted, as has been done in Table 3 of the paper. A direct determination of the restraining moments for such cases as those of Table 3, when a beam carries a uniformly distributed load, can be made by a simple graphical construction given by Professor Batho in the Second Report of the Steel Structures Research Committee, previously mentioned. If *OPQ*, Fig. 36, is the relation between angular rotation and moment for the connections, as determined by experiment, and if *OA* is measured off equal to M_F, the moment at the end of the beam which would cause complete fixity (that is, $\frac{WL}{12}$, in which W is the total load on the beam and L is its length), and *OB* is measured off equal to $\frac{M_F L}{2\,EI}$, and

AB is joined, the point of intersection, *P*, of this line with the curve, *OPQ*, gives the end-restraining moment directly.

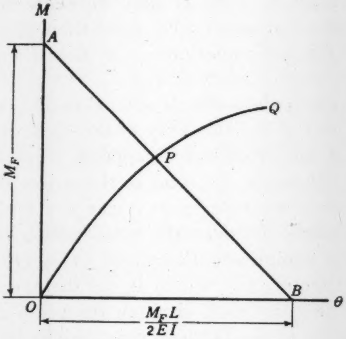

FIG. 36.

Mention has been made in Professor Rathbun's paper of the use of mechanical methods of stress analysis. Considerable attention has been given to this by the Steel Structures Research Committee. An attempt was made to use the deformeter on semi-rigid frames, the connection being obtained by reducing the rigidity of the beam as suggested by Professor Rathbun. This was found to be unsatisfactory due probably to the difficulty of making the necessary reduction with sufficient accuracy and also to the creep of the celluloid at the reduced section. A perfectly satisfactory direct loading method,[13] was evolved, however, in which the connections were made up in much the same manner as they are in practice.

L. E. GRINTER,[14] ASSOC. M. AM. SOC. C. E. (by letter).—It is encouraging that another writer has thrown the weight of his opinion, backed by the evidence of his tests, upon the side of those engineers who have continually insisted that riveted steel structures should be designed for partial continuity based upon the actual conditions of restraint. It is further encouraging that the author's tests present data that make it possible for one to estimate the probable restraint for a considerable range of beam sizes and types of riveted connections. Many more data of this kind are badly needed by the profession. In a country in which the annual construction program is several billion dollars, one has difficulty in understanding why the engineer must guess at such factors as end restraint when the cost of a comprehensive series of tests would be insignificant by comparison.

The tests presented are mainly on specimens of the connected beam type. Only Specimen 18 contained a column section between the beams. Hence, one must keep this fact in mind when using the author's data. It is evident that a girder-to-column connection will permit a greater total rotation than a girder-to-girder connection because of the duplication of tension rivets and the deformation of the column section. This effect can be evaluated for a specific case from the author's data. Specimens 18 and 15 have identical connections except for the insertion of the column section into the former. The moment-rotation curves, Figs. 21 and 23, show that Specimen 18 permitted an average rotation of about 20% more than Specimen 15. Of course, one could not expect this same relationship to hold for joints of considerably different types.

---

[14] Prof. of Structural Eng., Agri. and Mech. Coll. of Texas, College Station, Tex.

Of particular interest is the author's extension of the theory of continuous structures to take account of the elasticity of the connections. Much of the apparent complication of the procedure disappears when one has mastered the terminology involved. However, it seems to the writer that further simplification would be permissible without in any way destroying the true value of the analysis. For instance, consider the introduction of the terms, (*a*), (*c*), and (*e*), which greatly complicate Equations (17), (18), and (19). For all practical purposes the factor, (*a*), which is the distance from the face of the column connection to the first rivet through the beam flange, and the length, (*e*), which is the distance to the farthest rivet, might be taken as zero. Then, the factor, (*c*) = (*e*) − (*a*), would also be zero, and the effect upon Equation (18), for instance, would be as follows:

$$L_2 = L - 3\,e\left(1 - \frac{e}{L}\right) + \frac{b\,c}{2\,L^2}\,(3\,b + c) + 3\,E\,I\,Z\left(1 - \frac{a}{L}\right)$$

which becomes,

$$L_2 = L + 3\,E\,I\,Z \qquad \text{(43)}$$

when (*e*) = (*c*) = (*a*) = 0.

The physical significance of the suggested change is simply that the elastic action of the connection is assumed to be concentrated at the end of the beam instead of being distributed over the length of the end connection. Since there is still much to be learned about the true action of the connection itself, it seems quite as reasonable to the writer to assume that the elastic properties of the connection are thus concentrated. Undoubtedly, one could design special connections for which the assumption of zero length for the connection would be about as accurate as the author's procedure, which is based upon the assumption of uniform distribution of shear between rivets and a straight-line variation of beam moment within the length of the connection.

In order to demonstrate the insignificance of any error involved in the assumption of zero length for the connection, the writer has prepared Fig. 37, which is an analysis of the author's continuous beam example shown in Fig. 31 and analyzed in Fig. 33. The revised constants are determined, as follows:

$$L_{2BA} = 240 + \frac{3 \times 3 \times 10^7 \times 795.5}{10^8 \times 2.9} = 486$$

$$L_{2BC} = 120 + \frac{3 \times 3 \times 10^7 \times 215.8}{10^8 \times 4.2} = 166$$

$$A\,\overline{x}_{AB} = \frac{w\,L^3}{24}\,\frac{100 \times 20 \times 240^3}{24} = 1\;152 \times 10^6$$

$$A\,\overline{x}_{BC} = A\,\overline{x}_{CB} = \frac{100 \times 10 \times 120^3}{24} = 72 \times 10^6$$

$$M_{BA} = -\frac{3\,A\,\overline{x}}{L\,L_{1BA}} = -\frac{3 \times 1\,152 + 10^6}{240 \times 486} = -\,29\,500$$

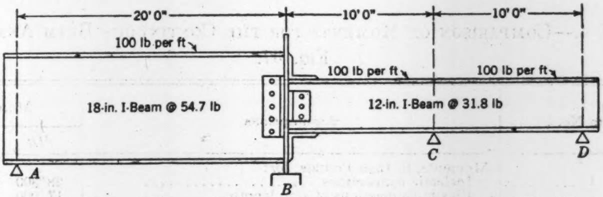
$$M_{BC} = +\frac{6\,A\,\overline{x}}{L\,(4\,L_2 - L)} = +\frac{6 \times 72 \times 10^6}{120\,(664 - 120)} = +\,6\,600$$

$$M_{CB} = -\frac{6\,A\,\overline{x}\,(2\,L_2 - L)}{L^2\,(4\,L_2 - L)} = -\frac{6 \times 72 \times 10^6 \times 212}{120^2 \times 544} = -\,11\,700$$

and,

$$M_{CD} = +\frac{3\,A\,\overline{x}}{L^2} = +\,15\,000$$

Signs agree with the writer's convention[15] that an end moment tending to rotate an adjacent joint clockwise is positive; the reversed moment is negative.



Stiffness Factors	1.63	1.59	2.19	1.80

FIG. 37.—CONTINUOUS BEAM ANALYSIS FOR ELASTIC CONNECTION OF ZERO LENGTH AT JOINT *B*

The carry-over factor is different from + 0.5 for the left end of Beam *BC* where it is $\frac{L}{2\,L_2} = \frac{120}{2 \times 166} = 0.361$.

The stiffness factor for each beam is, as follows:

$$K_{BA} = \frac{I}{L_1} = \frac{795.5}{486} = 1.63$$

$$K_{BC} = \frac{4\,I}{4\,L_2 - L} = \frac{4 \times 215.8}{664 - 120} = 1.59$$

$$K_{CB} = \frac{4\,L_2\,I}{L\,(4\,L_2 - L)} = \frac{4 \times 166 \times 215.8}{120 \times 544} = 2.19$$

and,

$$K_{CD} = \frac{I}{L} = \frac{215.8}{120} = 1.8$$

---

[15] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 15.

A comparison of the results obtained by three analyses of this continuous beam is given in Table 4. It becomes evident from this study that the probable error involved in treating the elastic end connection as of zero length would be of no great importance in the design of an ordinary structure. The important fact (which is usually neglected) is that the elasticity of the end connection produces changes in moments of between 30 and 40% at both Point *B* and Point *C*. As compared with this large discrepancy, the small effect of the length of the end connection becomes of little importance.

It is interesting to speculate upon the difficulties involved in extending the author's treatment of the simple three-span beam involving only a single elastic connection to a continuous frame with a dozen or more semi-elastic joints. Evidently, the labor involved would be a rather serious matter by any of the theoretical methods suggested by the author. In fact, a practical study would seem to be limited to the assumption that the moment-rotation curve remained a straight line or that the connection remained elastic within the limit of working stresses. The same limitation would necessarily apply to a deformeter study because it would clearly be impossible to represent the curved diagrams of the published tests by a stress-strain curve of celluloid. However, despite these apparent limitations, the author has performed a great service in calling attention to the serious effect upon moments and stresses that may be involved in the neglect of the elasticity and plasticity of the connections.

TABLE 4.—COMPARISON OF MOMENTS FOR THE CONTINUOUS BEAM ANALYZED IN FIG. 37.

C. R. YOUNG,[16] M. AM. SOC. C. E., AND K. B. JACKSON,[17] ESQ. (by letter). —Within the scope of his tests the author has done a remarkably useful and convincing piece of work, and the rotations found for the connections tested can be used, no doubt, for estimating the probable behavior of similar details under certain conditions A more complete diagnosis of the cause of the rotations obtained, however, would have served the useful purpose of indicating the most effective remedies.

The design of the specimens raises certain questions in the minds of the writers who, some time ago, conducted a somewhat similar series of tests. The variety of types and sizes adopted by the author is most comprehensive, but it would have been desirable also to vary the length of the specimens in order to obtain the moment-shear relationship that exists in the simulated beam of length, $L = 12\ d$. Moreover, the column used in Specimen 18 was too short to develop its normal restraint on the connection.

---

[16] Prof. of Civ. Eng., Univ. of Toronto, Toronto, Ont., Canada.

[17] Asst. Prof. of Applied Physics, Univ. of Toronto, Toronto, Ont., Canada.

Some difference of opinion may also arise as to the effect on the angular rotation of the omission of shear connections. The form assumed by the stems of the T's in flexure will not be the same for the top and bottom attachments. For the former the stem pulls away from the beam flange between the end of the beam and the first pair of rivets in it, whereas for the latter the contact is firm from the end of the beam to the end of the connection. The curves of the two stems being different, additional rotation will naturally arise.

The method of measurement is also open to criticism. Stress distribution must be particularly irregular in all these specimens, and, therefore, the method of attaching the Ames dials and the location of their stem contacts are matters of first importance. In Series *B* and *C* (Fig. 6), the special device for holding Dials *E* to *L* required sleeve-jointed spring points; it was attached to the beam flange near the inner end of the connection, and the stem of the dial was kept in contact with a surface that moved transversely due to vertical shear. Can such mounting conditions warrant measurements to 0.0001 in.? Dials *M* to *P* were clamped to that section of the flange, just outside the connection, where buckling would first occur and the transverse movements of the dial stems on the plate due to flexure and shear might well excuse the inclusion of the results.

The writers are of the opinion that more reliable results are to be obtained by measuring the relative rotation of cross-sections of the beams beyond the local effects of the connections by means of flange extensometers that encircle the plate or column, and comparing them with similar measurements made on an uncut beam specimen similarly loaded. Intermediate extensometer measurements may be made to locate the sources of the rotation obtained, for example, elongation of the column flange tension rivets, flexure in the T, or deformation of the shear rivets in the beam flange. An independent check may be obtained by deflectometer measurements.

As the author has suggested, much additional information might have been obtained regarding the behavior of these connections from the systematic application of normal and reversed loads. Only by this means is it possible to dissociate the effects of flange attachment and stress on deformation and to detect the extent of elastic and non-elastic slip.

The phenomenon of greatly increased rotation on the first reversal of load for Specimen 14 is characteristic of riveted specimens. The reason for it is, of course, non-elastic slip. Had the reversal of loading been continued until the specimen reached a steady deformational state the rotation would have been the same for reversed load as for normal load.

It would be interesting to know to what relative extent the tension and compression attachments contributed to the rotation. The results of the writers' investigations indicate that the tension attachment is responsible for from 20% to 50% more deformation than the compression attachment.

In seeking ways and means of improving end restraint, especial attention should be given, therefore, to the capacity of an attachment to resist tension with a minimum of yield.

University of Toronto Tests.—Incidental to an investigation of the degree of restraint developed at the ends of steel beams and girders with welded connections, a study was made of the rigidity of four riveted T-connections of two types at the University of Toronto, at Toronto, Ont., Canada, in 1930–32.[18]

The connections were similar to those of the author's Series *C*, Specimens 14 and 15, except that shallow welded shear connections were added. They consisted of T's cut from 30-in., 149-lb, Bethlehem I-beams, connecting two 18-in., 47-lb. Carnegie beams to a central 1-in. plate for two duplicate specimens, and to the flanges of a 4-ft length of 12 by 12-in., 110-lb, Carnegie H-beam for two other duplicate specimens. For convenience, connections of the first type may be termed "plate specimens" and those of the second type, "column specimens." For the former, $\frac{7}{8}$-in. rivets were used throughout, but since the grip of the rivets in the flange of the T's was considerably less for the column specimens than for the plate specimens, they were made $\frac{3}{4}$ in. in diameter, the better to balance the design. This was in conformity with the expected strength of tension rivets of different grips, as indicated by tests made some years ago at the University of Toronto.[19]

A nominal factor of safety of between 2.25 and 2.50 was used in the design of rivets, selection of the working stresses being made with a view to rendering failure of the rivets more likely than failure elsewhere. Although the factor of safety adopted by the author for his Specimens 14 and 15 is not mentioned, it appears to have been greater than the foregoing.

Unlike the author, the writers distrusted the vertical shear rigidity of T's and, consequently, in order that the angular rotation of the connections at the face of the support might not be unduly influenced by vertical shear deformation, or that shear failure might not precede moment failure, two shear plates were welded on the web of each beam for all specimens, with a factor of safety of 3.4 in the welds.

In order to study the characteristics of the connections plain beam specimens corresponding to the cut-and-connected specimens were tested in exactly the same manner, and the effect of the connections was determined by differences.

Instruments.—Two types of instruments were used to measure the deformation of the specimens: (*a*) Yoke extensometers, with accessories, to measure horizontal deformation between points on or near the flanges of the beam; and (*b*) deflectometers, with accessories, to measure the vertical movement of points on the neutral axis of the beam.

Whereas the author measured his deflections with respect to a bar resting on rods fastened to the ends of the specimen, the writers measured the vertical movement of points on the neutral axis of the beams as related to a bridge hung from, and aligned at right angles to, the central vertical element of the specimen. Yokes carrying Ames dials were fixed to the specimens at the neutral axis and were of such length that the plungers of the dials bore on the bridge. The particular advantage of this method of measurement was that it gave the deformation of each half of the specimen with respect to the central vertical section separately, and, in the case of the connected specimens, indicated the relative rigidity of the two connected cantilevers.

---

[18] "The Relative Rigidity of Welded and Riveted Connections," by C. R. Young, M. Am. Soc. C. E., and K. B. Jackson, *Canadian Journal of Research*, July and August, 1934.

[19] "Permissible Stresses on Rivets in Tension," by C. R. Young, M. Am. Soc. C. E., and W. B. Dunbar, *Bulletin No. 8*, Section No. 16, School of Eng. Research, Univ. of Toronto, 1928.

Test Procedure.—Although a loading in only one sense is required to determine the degree of restraint or continuity developed by a connection, a reversed loading is necessary for a wind-bracing connection, which may be subjected to complete reversal of stress, possibly involving both elastic and non-elastic slip. Furthermore, initial set occurring during the first load alters the behavior of the specimen during subsequent loads. Consequently, to determine the final rigidity of a wind connection, an adequate series of loads must be applied to eliminate initial set, and to reveal the full value of slip due to reversal of load, as well as the normal elastic deformation of the specimen. Inasmuch as the author's tests do not involve reversal of load (except in one incidental case) his rotation angles cannot apply strictly to wind connections after the first change in wind direction.

To fulfill the requirements mentioned each specimen was subjected to five loads applied and released in 5 000-lb. or in 10 000-lb. stages, from 0 to 75 000 lb, and a sixth load to failure. The first two loads, termed "normal loads," were applied so that the connection was stressed as by a gravity load in the simulated beam. The third and fourth, termed "reversed loads," were applied in the opposite direction, and the last two loads were again normal loads. Readings on the four extensometers and six deflectometers were made after each stage in the application and release of each load.

Results.—In the writers' investigation an effort was made to discover the sources of the deformation, an inquiry that the author did not attempt. For purposes of analysis the connections were divided longitudinally into three regions, I, II, and III, and transversely into two halves termed the top and bottom flanges. Region I comprises the half width of the column and, consequently, existed only for column specimens. Region II extended from the face of the plate or column 2½ in. along the specimen, and Region III extended from the section at 2½ in. to one at 12 in. from the face of the plate or column. For the plain beam specimens the origin was at mid-span. In referring to the specimens it was sometimes found convenient to group all three regions into one region—VI.

The flexural slope developed in a given flange and region is determind by: (1) The type of connection; (2) the flange included, top or bottom; (3) the stress involved, tension or compression; and (4) the loading sequence, including or excluding non-elastic slip.

In some types of connections the effect of a change in Factors (2), (3), or (4) is small, while in others it is considerable. A comprehensive test of any type of connection, therefore, must involve both flanges in both kinds of stress and the loading sequence must be such as to include any non-elastic slip that may occur. Consequently, the application of one-direction loads, as in the author's tests, can not yield the final answer to the problem of wind-bracing rigidity. It was for this reason that the writers adopted a load varying from capacity loading in one direction to capacity loading in the other direction.

Analysis of the flexural deformation occurring in each flange and region of the specimens under the reversing design load, combined with the evidence obtained during failure loads, forms the basis of certain observations which attempt to explain the deformations indicated in terms of the structural details involved.

In Region I the most obvious deformational characteristic was that the tension half of the connection was the critical element. Elastic slip was slightly greater in compression than in tension, but was about twice as great in the top flange as in the bottom. Proportional deformation was 2.6 times as great in tension as in compression, but only slightly greater in the top flange than in the bottom. This excessive deformation in tension is due to the outward bending of the column flanges and the elongation of the connecting rivets.

The deformations in Region II included longitudinal deformation of the attachment within 2½ in. of the column face, bending of the T-flanges, and deformation of the connecting rivets. The deformations of the top and bottom flanges were very similar in the riveted specimens, for which the top and bottom attachments were the same.

The deformations indicated for Region III included the longitudinal deformation of the attachment and beam, and the shear deformation of the connecting rivets or welds with any slip that might have occurred. Non-elastic slip produced more than one-half the deformation and constituted nearly one-third of the total deformation of this type of connection, elastic slip was negligible, and proportional deformation was similar to that of the plain beam.

An analysis of the deformation in Region VI disclosed the particularly interesting fact that for plate and column specimens the deformation arising in Region III is 75 and 50%, respectively, of the deformation in the entire connection. This substantiates Professor Rathbun's observation of marked deformation in the rivets through the beam flanges in the case of certain of his specimens.

Analysis of the total flexural deformation that occurred in each type during the reversing load and the relative effect of tension and compression, top and bottom flanges, and normal and reversed loads in producing it, justifies the following observations: (1) About 30 to 45% of the deformation consisted of non-elastic slip; (2) the aggregate elastic deformation in tension was from 56 to 70% greater than that in compression; (3) opposite flanges deformed equally; and (4) the deformations under normal and reversed loads were identical.

Coefficients of Restraint.—The coefficients of restraint (that is, the relation between the end moment developed in a uniformly loaded beam and the fixture moment), was first found for the initial load assumed as carried to failure. Account was thus taken of initial set, or slip, or both. Obviously, this is the correct loading for total moment calculations, as unrecoverable deformation in the connections permanently lessens their participation in the total moment developed in the span.

Although coefficients of restraint greater than unity are found for welded specimens, the values for riveted T-specimens were less than this. For the plate specimens, it ranged from 0.99 for 0.2 of the design load to 0.93 at the design load. For the column specimens, it ran from 0.92 at 0.2 of the design load to 0.84 at the design load. Above the design load the values dropped off rapidly. Calculations show that for Professor Rathbun's Specimens 14 and 15 the coefficients of restraint at design loads were 0.96 and 0.73, respectively; for uniformly distributed gravity loads the ideal value, 0.75, permits an increase in load of 100 per cent.

A more typical situation with respect to end restraint arises when any one of the innumerable loadings following the initial load is applied. The connections have then suffered permanent deformation and permanent impairment of their restraining value. Calculations of the coefficient of restraint, therefore, should include a constant amount for the permanent deformation resulting between the beginning of the intial load and the beginning of the repeat load.

As was to be expected, the development of a large permanent deformation during the early loads reduced the coefficients of restraint under the repeat load in its early stages to values much less than those for the initial load. For the plate specimens, it varied from 0.63 at 0.2 of the design load to 0.9 at the design load; for the column specimens, it was much lower, varying from 0.3 at 0.2 of the design load to 0.75 at the design load.

Factors of Safety.—The plate specimens failed by flange buckling, with an average ratio of test factor of safety to design factor of safety of 0.97. The column specimens failed by rupture of the tension rivets, with an average ratio of test factor of safety to design factor of safety of 0.89. The rivets failed at an average tension of 26 900 lb each, or 61 000 lb per sq in., based on the size before driving, as compared with an assumed ultimate strength in pure tension of 30 000 lb. The fact that the column specimens gave smaller relative factors of safety than the plate specimens was due, no doubt, to a lesser uniformity of stress distribution among the tension rivets connecting the T to the column flange. Furthermore, the shorter grip of the smaller rivets in the column flange failed to compensate for their use in the column specimens and for the leverage effect of the pressure at the toes of the T. As the moments on the author's comparable specimens did not produce rivet tension in excess of 55 100 lb per sq in. (Specimen 15), the influence of flange bending and leverage on ultimate tensile strength was not disclosed.

Effective Slope Angles Due to Connections Only.—So far as the effect on positive moment in the beam or on story drift is concerned the slope angle due to the connection may be taken as the difference in flexural slope, at any section beyond the connection, between a beam integral with the column and a similar cut-and-connected beam under the same load.

For a load producing a moment varying from capacity positive moment to capacity negative moment, the slope angles attributable to the connections alone, were found by the writers to be 0.00222 radian for the plate specimens and 0.00492 radian for the column specimens. It is to be noted that in each case the shaft of the column is assumed to be straight, and that although local bending in the simulated column web is not included, bending in the column flange is included.

For a capacity moment in one sense only the values of the slope angles may be taken as one-half those given for the reversing load. The mean value for plate specimens under a load in one direction only (that is, 0.0011 radian) is approximately equal to that obtained by Professor Rathbun on reloading Specimen 15 at a moment of 40% of the ultimate moment, which was the ratio of design to probable ultimate load observed in the Toronto tests. It is not possible to make a similar comparison with the author's single-column specimen, No. 18, as the ultimate moment is not given.

E. MIRABELLI,[20] M. AM. SOC. C. E. (by letter).—In Table 3 the author intimates that the carrying capacity of beams under gravity loading may be increased by as much as 95% by making use of the end restraint provided by the connections. This percentage approaches, very closely, the theoretical maximum of 100% which would occur with a perfectly balanced design when, under full working load, the connections yield just enough to make the bending moment at mid-span equal to the restraining moment at the connections. Such percentages may lead to unwarranted optimistic conclusions regarding the extent to which economy is possible in an actual design. The possibility of extremely large savings from utilizing resistance of connections is doubtful for an ordinary building frame, for the following reasons:

(1) The elasticity of the connections differs from that of the remainder of the beam and, as a result, the stresses developed in the beam are not proportional to the applied load. The bending moment at mid-span increases more rapidly than the loading, whereas the bending moment at the end increases less rapidly than the loading. The variation for Specimen 10 (see Table 3) is shown by the calculated curves in Fig. 38. Because of this characteristic, the factor of safety based on unit stresses is larger than that based on loading. For example, if the factor of safety is 2 measured to the yield point for the beam of Fig. 38, the resisting moment at the yield-point stress is twice that at the working stress. As indicated by the broken lines, the applied load at the yield point is less than twice the working load. The factor of safety based on loading for the case shown is only 1.78, whereas the stress intensities indicate a factor of 2.00. The importance of dealing with applied loads rather than with unit stresses may be appreciated

---

[20] Asst. Prof., Structural Eng., Mass. Inst. Tech., Cambridge, Mass.

if an extreme case is considered in which the increase in moment is so rapid that an increase of, say, 5% in loading beyond the working load causes the bending stress to be doubled.

The percentages of permissible excess loading shown in Column (19) of Table 3 were computed with the factor of safety based on unit stresses. Table 5 indicates how some of these percentages are reduced if the factor of safety is based on applied loads. The allowable excess load is reduced by an average of about 30 per cent.

16	22	127.6	248.0	202.0	94	58
18	16	108.1	206.0	188.2	91	74
..	..	.....	.....	.....	....	....

(2) The author's percentages are based on the use of perfectly rigid supporting columns. Flexibility of the columns has the effect of reducing the allowable excess loading. The greatest effect from this source is likely to be in the upper stories of a building where column sections are relatively small, and the least effect is in the lower stories of a tall building where column sections are large.

(3) Bending moment in the beams of a building frame is reduced at the expense of the columns. Unless the arrangement is such that the end moments in adjacent beams balance each other, the restraining moments are transferred to the columns, and much of the saving in material of beams may be offset by an increase in required material for columns.

(4) Table 3 was compiled for uniform loading which leads to more favorable results than concentrated loading. As an illustration, with a concentrated load at mid-span the percentages for Specimens 10 and 15 in Table 5 are changed from 55 and 95 to 43 and 68, respectively, and Percentages 37 and 71 are changed to 31 and 55, respectively.

(5) From the possible economy in material must be deducted the added cost of the more complex analysis involved in the use of end restraint. The method of analysis undoubtedly would be simplified through experience, but would always be more costly than the analysis with unrestrained connections.

Regardless of whether or not very large savings can be accomplished, information of the type given in this paper is of great value in providing an essential "missing link" in the precise determination of stresses in building frames.

R. L. Moore,[21] Esq. (by letter).—In view of the emphasis that has been placed on methods of analyzing continuous frames, it seems that the question of joint rigidity in riveted structures has received too little attention. The author of this paper has made a valuable contribution to the knowledge in this field.

From the standpoint of design, the evaluation of the rigidity of the joints in terms of total fixity has certain advantages over the procedure outlined by the author, particularly where the method of moment distribution is used. It may be shown that the distribution factors for any joint are proportional to the product of the $\frac{I}{L}$-values and the degrees of fixity for the members at that joint. It also follows that the carry-over factors at one end of a member are equivalent to one-half the degree of fixity at the other end. After computing fixed-end moments and making adjustments for the estimated degrees of fixity at the joints, the procedure becomes one of simple moment distribution. The author's illustrative problem, shown in Fig. 33, may be solved readily in this manner. On the basis of the results presented in this discussion, however, the writer would alter somewhat the values for the fixed-end moment used. The author has assumed M_{BA} and M_{BC} in Fig. 33, to be the equivalent of about 50% and 70% fixed, respectively. Although the latter percentage is in accord with the writer's tests, the fixity for the clip-angle connection on the 18-in. I-beam, on the same basis, would not be taken at more than about 20 per cent.

---

[21] Research Engr., Aluminum Research Laboratories, Aluminum Co. of America New Kensington, Pa.

In the tests upon which these conclusions are based, two-span continuous beams, having a joint or splice at the center support, were used. By comparing the behavior of such specimens with that of an unspliced beam, having 100% continuity, a direct measure of the efficiency of the joints in transmitting bending moments was obtained.

Figs. 39 and 40 show the eight specimens on which tests were made. Specimens 1 and 2 were representative of cases of 100% and 0% continuity, respectively, whereas Specimens 3 to 8 included several common types of beam connections. All specimens were 10 ft 6 in. in over-all length and were made of 8-in. aluminum alloy I-beams and aluminum alloy angles and plates. The section elements of the I-beams were as follows:

The tensile properties are listed in Table 6. The joints were fabricated by means of hot-driven steel rivets $\frac{5}{8}$ in. in diameter. The make-up of each may be described briefly, as follows:

Specimen	Type of Joint
3	Four clip angles, 3 by 3 in. by $\frac{3}{8}$ in. by 6 in. long.
4	Four clip angles, 3 by 3 in. by $\frac{3}{8}$ in. by 6 in. long. Two splice-plates, $\frac{7}{16}$ in. by 4 in. by 8 in.
5	Four clip angles, 3 by 3 in. by $\frac{3}{8}$ in. by 6 in. long. Two splice-plates, $\frac{7}{16}$ in. by 4 in. by 1 ft long.
6	Four clip angles, 3 by 3 in. by $\frac{1}{2}$ in. by 6 in. long. One connection of the joint riveted; the other pin-connected (diameter of pin, $1\frac{1}{2}$ in.).
7	Four clip angles, 6 by 3 in. by $\frac{1}{2}$ in. by 10 in. long.
8	Four clip angles, 3 by 3 in. by $\frac{3}{8}$ in. by 4 in. long. Four seat angles, 3 by 3 in. by $\frac{1}{2}$ in. by 6 in. long.

Fig. 41 shows the nature of the two-span beam tests. The reactions on the auxiliary loading beam of the testing machine used (capacity, 300 000 lb) were 5 ft, center to center, whereas the loads on the specimen were applied at the center of each span. Deflections were measured by a dial-gauge graduated to 0.001 in., with respect to a reference beam under the specimen, as shown in Fig. 41. Stresses were determined by a 2-in. strain-gauge, readings

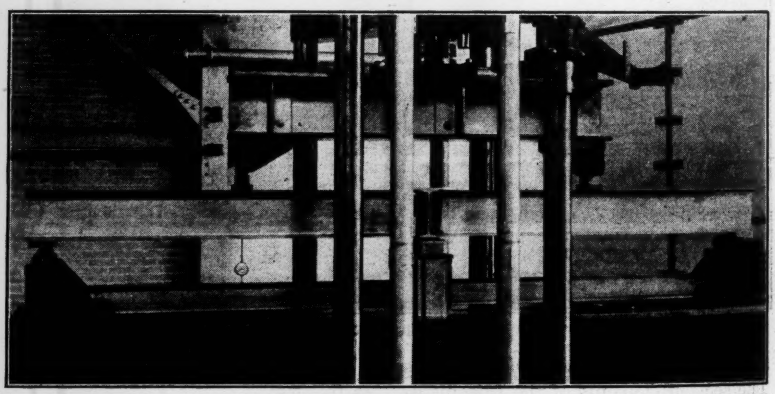

FIG. 41.—TWO-SPAN BEAM TEST OF SPECIMEN 4.

being taken on the top and bottom flanges at a sufficient number of sections to determine the distribution of bending moments.

As a preliminary step in the investigation, deflections and permanent sets were determined for each specimen for loads up to 30 000 lb. The beams were then turned over and the procedure was repeated. The behavior was similar in both cases, and permanent sets were on the order of only 0.002 to 0.004 in.

at the joints over the center supports to those observed in Specimen 1 gave a direct measure of the continuity factors or joint efficiency for each type of construction. From the results given in Table 7 (*a*) it will be noted that none of the joints was the equivalent of an unspliced beam. The highest degree of fixity — 95% — was found for Specimen 5, which had long splice-plates in addition to web clip angles. Continuity factors for the other spliced specimens ranged from 72 to 12%, the latter being found for Specimen 6 which had one span pin-connected near the joint. The standard clip-angle connection in Specimen 3 developed about 19% fixity.

Fig. 43 shows the influence of joint fixity upon the deflections of the different specimens. The relative positions of the curves will be recognized as about the same as those shown in Fig. 42 for the bending moments. The average measured center-span deflection of Specimen 1, being 100% continuous, was only 58% of that observed for the two simple spans of Specimen 2, whereas all the deflections of the other specimens were between these limits. Although the deflection measurements obtained were not sensitive enough to the degree of fixity at the center support to be used in determining continuity factors, as was done in the case of the bending moments, the agreement between the measured and the computed values given in Table 7 (*b*) was reasonably good.

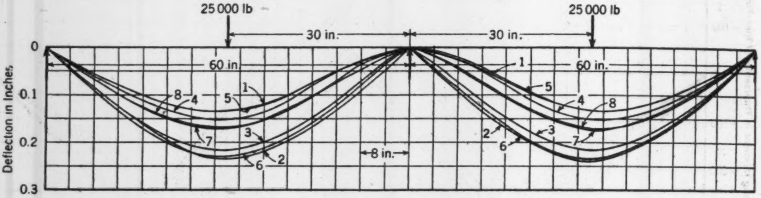

FIG. 43.—COMPARISON OF DEFLECTIONS FOR A 50 000-POUND LOAD.

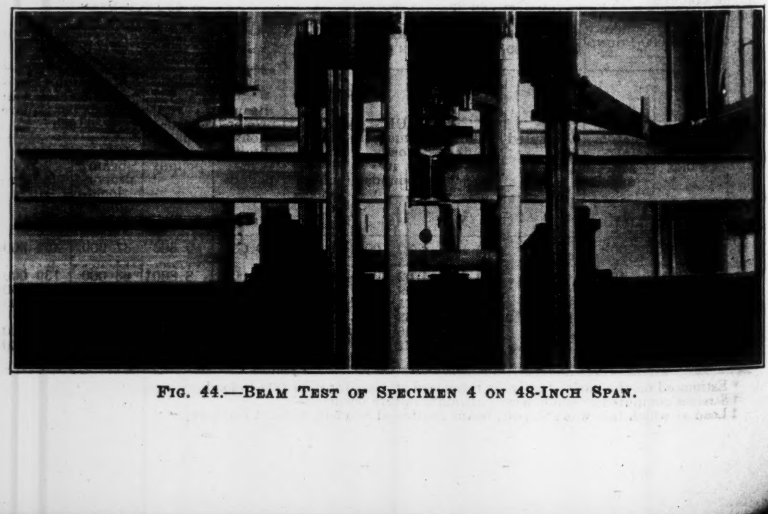

FIG. 44.—BEAM TEST OF SPECIMEN 4 ON 48-INCH SPAN.

In comparing bending moments and deflections for a single 50 000-lb load, attention should be called to the fact that both were proportional to the loads applied up to approximately the point of failure. The latter occurred in every case by a lateral buckling of the compression flanges of the beams without any apparent injury to the joints. Table 7 (*c*) gives the ultimate loads carried and the corresponding maximum computed flange stresses at the centers of the spans.

Since none of the specimens was damaged in the two-span tests all but Specimens 2 and 6, which did not have rigid joints, were subjected to a simple beam test on a 48-in. span as shown in Fig. 44. The purpose of this test was to determine more nearly the ultimate bending resistance of the joints. Table 7 (*d*) gives a summary of the maximum loads carried and the corresponding computed stresses at the points where failure occurred. The manner of failure in each case was, as follows:

Specimen	Type of Failure
1	Lateral buckling of the flange accompanied by the buckling of the web at the center load point.
3	Yielding of the web in bearing, around the clip-angle rivets.
4	Shearing failure of the rivets in the lower splice-plate.
5	Tension failure of the lower splice-plate.
7	Tension failure of the web at the outside line of rivets.
8	Shearing failure of the lower seat-angle rivets.

It is significant that with one exception (Specimen 7) the moments resisted in the simple span tests were from about 70 to 90% higher than those developed in the two-span tests. Furthermore, it appears that this bending resistance may be safely estimated on the basis of the ultimate strength of the material at the point subjected to the maximum stress.

Although it is appreciated that these tests have been limited to comparatively few specimens, the results obtained do indicate some useful limits for design purposes. For standard clip-angle connections it appears that a degree of fixity of from not more than 20 to 40% may be expected, depending upon whether single or double lines of rivets are used in the web. The use of seat angles in addition to clip angles on the web may increase continuity factors up to 50% or 60%, whereas the use of splice-plates on the flanges may result in continuity factors of from 75 to 100 per cent. In using these percentages, it is obviously essential that the joints be made sufficiently strong to carry the moments attributed to them. It should be pointed out that these percentages are in substantial agreement with the results indicated in Table 3 of the paper. The 15% increase in carrying capacity of Specimen 4, for instance, corresponds to a joint fixity of about 20%, as given herein for standard clip-angle connections. The increase in carrying capacity of Specimens 11 and 12, having seat angles, corresponds to a joint fixity of about 60 per cent. Although none of the writer's tests included specimens similar to those in Series *C*, the joint efficiencies obtained for this type of construction ranged from about 65 to 100 per cent.

John Sanford Peck,[22] **M. Am. Soc. C. E.** (by letter).—Under "Description of Tests and Failures" (see following Fig. 11) the author states: "The curve obtained was of an entirely different type from that of the others in this entire series of tests. This curve suggests a subject for further investigation." He was referring to Specimen 14, Run 3, in which a specimen that had been tested beyond the elastic limit, but not to destruction, was loaded in the reverse position, thus simulating the condition arising in a wind-bracing connection when the direction of the wind changed 180° (see Fig. 3(*b*), Specimen 14, Run 3.). A further inquiry into this condition, therefore, is justifiable. Two types of connections were fabricated for testing in the laboratory of the College of the City of New York, identical with Specimens 13 and 14 (see Fig. 1), except that the over-all length was 10 ft instead of 6 ft. Two specimens of each type were made up, the entire investigation thus comprising tests of two pairs of specimens.

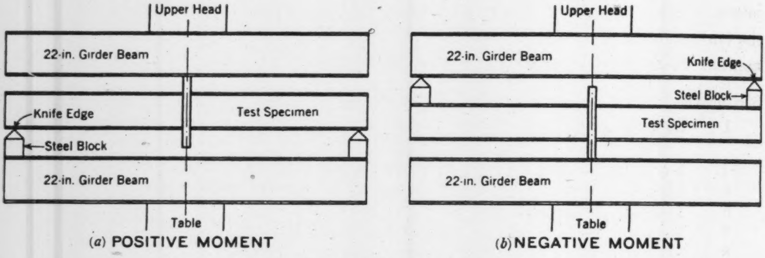

Fig. 45.—Method of Loading.

The experimental technique was identical with that followed by the author. The dials used in measuring the angular rotation were placed as shown in Fig. 6, except that Dials *M*, *N*, *O*, and *P*, were omitted. The method used to reverse the direction of the application of the load is shown in Fig. 45, the knife-edges, *AA*, being changed from the bottom to the top position when it was desired to change the direction of loading.

---

[22] Asst. Prof. in Chg. Materials Testing Laboratory, School of Technology, Coll. of the City of New York, New York, N. Y.

The specimens were loaded according to the schedule given in Table 8, the loads being the total applied to the central plate of the specimens. In Figs. 46(*a*) and 46(*b*), the angular rotation, expressed in radians, of the connection was computed by the same method as that used by the author, and the results of each side were averaged. The results from the tests of the two identical specimens were then averaged so that the data shown, represent the average of tests of four connections, respectively.

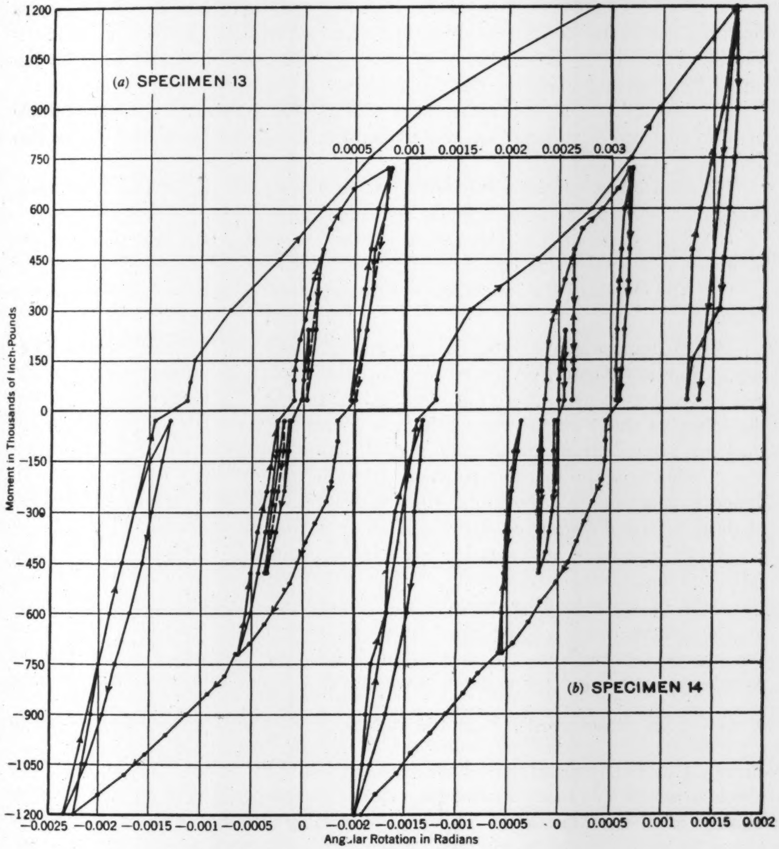

FIG. 46.—RESULTS OF TESTS ON SPECIMENS.

The writer presents these curves with the idea that the reader can draw his own conclusions from the data. The small number of tests involved makes it difficult to generalize too extensively on the action of wind-bracing connections under a reversal in wind direction. The tests do indicate trends which may be summarized, as follows:

(1) Under repeated loads in the same direction within the elastic limit, the connections behaved elastically because the re-loading curves may be considered to be straight, allowing for hysteresis effect.

(2) Under a reversal of the direction of loading, a slip occurred in the connection, due to some factor which was not determined in this investigation. (It might possibly have been the slackness of fit of the rivets in the holes.) After this slip had occurred the joint continued to behave elastically under repeated loads in the same direction and within the elastic range, until another reversal in the direction of loading, when a slip again occurred followed by a second phase of elastic behavior.

(3) Beyond the elastic limit there was a large increase in the magnitude of the slip on a reversal in the direction of loading and the connection deformed plastically.

(4) The effect of the additional row of rivets was to increase the resistance of the connections to angular deformation.

(5) The slope of the re-loading curves for equal positive and negative moments appeared to be equal.

(6) The slopes of the re-loading curves appeared to decrease with increasing moments.

Direct comparison of the data presented herein with those presented by the author is difficult for the reason that the conditions under which the two sets of tests were made were not identical. The use of a longer span decreased the effective shear on the connections as tested by the writer and, although it may be argued from theoretical consideration that the shear on the joint has no effect on the angular rotation, there is not sufficient experimental evidence supporting that point of view to warrant the comparison of two sets of data having different conditions of shear acting on the connections.

The writer's tests, however, do serve to accentuate a point which the author has failed to emphasize particularly. Figs. 46(a) and 46(b) show clearly that the slope of the reloading curve is not a constant quantity, but is dependent on the degree to which the joint has previously been strained. The author has chosen his coefficient, Z, such that $M Z = \theta$, in which θ is the angular rotation of the joint for a given moment, M. From the foregoing equation, $Z = \frac{\theta}{M}$, in other words, Z is the reciprocal of the slope of the re-loading curve. From an inspection of Figs. 46(a) and 46(b) it is readily seen that for a given moment there can be several values of Z depending upon the previous history of the connection. This is not clearly brought out by the author either in his curves or in his test. For one who is familiar with the interpretation of experimental data and the general technique of re-loading curves, the information is available with which to make that deduction, but it is doubtful whether the average reader is familiar enough with laboratory technique to be able to read that most important fact for himself from the data as presented, and it is to be regretted that the author did not bring the point out more explicitly. In view of the fact that Z is a variable coefficient that differs with the size and type of the joint and with the degree to which the joint has previously been strained, it would seem that the use of a numerical value for Z in actual steel design must be based upon the completion of a long series of laboratory investigations undertaken to determine its exact numerical values.

The author has undoubtedly made a major contribution to steel design in developing his theory of the elastic behavior of riveted connections, but the writer foresees a long period of necessary laboratory work running into several years before this theory can be used in practical designing. At present, those connections which developed relatively small resistance to moment (namely, Series A, Specimens 1 to 7), are taken as being free end beams whereas those connections which developed large resistance to moment (Series B and C, Specimens 8 to 14) are designed as completed fixed-end connections. The use of the author's method of design, therefore, would not affect the design of the clip-angle connections and would increase the amount of steel necessary in the wind-bracing connections; hence, the result would be less economy of steel than at present.

J. CHARLES RATHBUN,[23] M. AM. SOC. C. E. (by letter).—The discussions of this paper emphasize the fact that the problem presented was being studied in at least three other laboratories at the same time that the work was being conducted by the writer, indicating that the subject of stress analysis in steel frames has reached a stage where the properties of the connections should be considered. It is fortunate that the synopsis and reference of each of the works of the other investigators have thus been published in order that those who are interested further in this subject may read the originals if they choose. The writer undertook the experiments described in his paper because he was unable to find any data on the subject. Certain phases of the experiments touched upon by the discussers (such as the reversal of moment, the distribution of deformation among the parts of the connection, and the effect of shear) were omitted because they were not needed for the solution of the problem of which this investigation was a part.

Professor Goodwin has taken advantage of his familiarity with the writer's work and methods to clarify the paper in some respects, and his comments are appreciated. The question of signs is one that arises quite often in studies of this nature, partly because textbooks are often confusing on the subject. The system used by the writer for beams is to accept the conventional sign for moment on a beam as positive when the upper fibers are in compression. As E and I are always positive, the signs for shear, load, slope, and deflection follow at once by direct integration or differentiation of the mathematical expression for moment. Some confusion has arisen because the foregoing statement leads to negative loads when their direction of action is negative (downward) and to negative deflection when this deflection is downward. The desire to avoid these two situations is probably the reason for using other sign systems in computations. The convention for the signs of the moment tending to rotate a joint is used as positive when counter-clockwise for the reason that counter-clockwise angles, when small, have positive tangents. Thus, stress is proportional to strain and the signs are consistent in this relation. Those who wish to consider clockwise motion as positive will find no error in their work.

---

[23] Associate Prof., Civ. Eng., Coll. of the City of New York, New York, N. Y.

The beam and joint sign conventions cannot be consistent with each other at all times. In the case of a beam a counter-clockwise moment is positive at one end and negative at the other. The writer knows of no better method of minimizing this difficulty than the introduction of two self-consistent sign systems. As Professor Goodwin states if the reader is familiar with another sign system than that used by the writer the formulas are developed in the paper and it is a very simple matter to go over them changing the signs to the more familiar system. The writer feels that Professor Goodwin has done a service in clarifying this point.

Mr. Rowan and Professor Baker infer that the writer should have mentioned the work of Professor Batho[10] in his "Introduction". This omission was unintentional and was due to the fact that the paper was submitted before Professor Batho's report was available. The writer is in accord with Professor Baker that those who are working on any particular problem should be in closer touch with each other. Discussion reveals that the British Steel Works Association has been working on this subject for several years without the knowledge of those committees of the American Institute of Steel Construction and of this Society as well as of Columbia University, which were consulted during the investigation, or examined the writer's paper before it was published. At the same time, these organizations have been familiar with the plans of the investigation since 1931, and the tests have been advertised locally as they were conducted, so that those who were interested might view them and suggest ideas. It is unfortunate that practical difficulties prevent a closer co-operation in the advancement of the field in which several investigators are interested.

Professor Batho's work is similar in many ways to that of the writer. It contains many ideas not brought out in the paper or discussions. The duplication of the several tests is not an economic loss as a study of the additional number of tests lends weight to the value of the constants used in computations.

The remarks concerning the only possibility of connection failure being due to fatigue are not correct. A frame that consists of columns and beams under horizontal loads relies upon the connections for its strength unless they are stronger than the beam itself. It is true that failures of this type do not occur in buildings, probably because horizontal loads are not applied to buildings with as much force as would be necessary to cause the trouble suggested. The problem is of more than academic interest, however. One method of bracing for horizontal loads is to use wind-brace connections of the type of Series *C*, because such connections have a high resistance to moment.

Mr. Rowan's suggestion that column sections introduced between the connections would produce results of a different character is undoubtedly true. As there are so many combinations of column section and connections, the writer is of the opinion that the properties of columns as affecting the rigidity of joints can be made a separate study. The combination of connection and column can then be developed, as can the combination of several connections. The writer tested only one column, because his paper deals with connections. As Professor Grinter has indicated, some idea of the effect of columns can be obtained from this test. The field is full of subjects for investigation but, to be of value, a paper must confine itself to the subject under discussion. The subject of shear, therefore, was omitted from the paper, perhaps unwisely. The question of partitions and concrete in buildings is also entirely out of the province of the subject.

One reason shear has not been discussed is that the data of the tests have a wide spread. To conduct a series of tests varying the shear would involve considerable labor and might lead to a minor correction in the results which by their nature are erratic. If one is interested, this is a subject for separate investigation, but the writer feels that he has made his paper of sufficient length within its well-defined scope.

Shear angles were omitted on the connections of Series *C* in order to observe the effects of such omission. A study of the shear curves will give designing engineers the data from which they can decide whether or not such angles are necessary.

Mr. Rowan's remarks about "complete analysis" and "trial-and-error method" are not consistent with modern progress. Twenty-five years ago some engineers might have agreed, if they were strong opponents of the progress being made in stress analysis. As to the "trial-and-error" philosophy, the writer respectfully refers Mr. Rowan to the published opinions of Hardy Cross, M. Am. Soc. C. E.

Mr. Scholtz is to be congratulated in indicating how the labor of allowing for the connections can be reduced in an analysis. The writer feels that the improvements in this investigation that are to be made are in theory rather than in laboratory tests. Although more tests are always of value the digesting of these tests and the incorporating of their results in engineering design is another and more important matter.

Professor Batho's graphical method of analyzing connections is one that deserves a more complete treatment than the outline given in the discussion. It should help materially in popularizing the idea of including connection data in a frame analysis.

Both Professors Baker and Grinter suggest that some of the terms in Equations (15) to (21) could be omitted to advantage. This is the intent of the writer. Having given the several terms that theoretically affect the results, Table 3 is constructed so as to include these terms in the computations. If one does not wish to use the corrections, the consequent error can be approximated after a study of the table.

The writer is inclined to agree with Professor Grinter that in the practical case the moment-rotation curves may be considered as straight lines. In fact, the reloading curves are not far from straight. The experimental data indicate that after a connection has received some stress the reloading curves govern. This should tend to simplify the computations. The slope of the curve must be based on judgment after the probable history of the connection has been considered.

As the tests described by Professors Young and Jackson were conducted with objectives differing from those of the writer, a thorough study of their work should reveal many ideas not treated by the writer. The suggestion that the writer neglected the study of shear, for example, is mentioned by several of the discussers. To have made an investigation along these lines would have multiplied the number of tests, the number of specimens, the time, the labor, and the expense very much. The effect of shear, the writer feels, is small compared with the variation in the properties of connections of the same design. Consequently, he has left it for others to study.

Although the laboratory technique used by the writer differed from that of the several discussers, he feels that it was as satisfactory as the others. It was adopted after considerable study of the idea of fastening the instruments beyond the influence of the connection. No trouble was experienced with the dials slipping on the bands, due to shear deformation. The data were not recorded, nor the curves plotted to a degree of accuracy comparable to readings of 0.0001 in., and the writer does not wish to create the impression that the work was done with that refinement. Dials of this degree of accuracy were used because they were easy to read and were readily available.

The question of reversal of moments was considered while planning the series of tests made by the writer. This aspect of the subject was not studied for several reasons: One was that the paper had already assumed an excessive length; another was that an investigation of the deflection of one of the tall buildings in the City of New York (which deflected less than 6 in. in eighty stories during a 90-mile wind) led to the impression that the wind would not reverse the dead moment on a building connection under any but the most exceptional circumstances. The writer felt that he may have been in error in neglecting this phase of the problem and, therefore, a study of reversals was undertaken at the College of the City of New York as soon as the eighteen tests made by the writer were completed. These tests were made by Professor Peck who has presented his findings in a separate discussion.

The question of whether the top or bottom attachment is responsible for the largest percentage of deformation was not studied and was not treated in the paper although the necessary data were taken during the tests. This phase of the problem did not have a bearing on the work that the writer had in mind. As illustrated in the curves, the right half and the left half of the specimen each constituted a separate test of a connection. These tests were both plotted and published. This was also done in the case of reversed loading, but in the latter case, only the average curve is published, for the sake of clearness.

Professor Mirabelli demonstrates, by means of curves, the effect of the change in the properties of the connections as the load is increased, with the conclusion that the effect is less as the load increases. This is a material contribution to the paper. His statement that the writer's percentages are based on rigid columns is true; the necessary changes can be made when the design is known. This makes the data different from those of the problem investigated by the writer, with the result that different answers will be obtained.

The third point indicates that the transfer of the moment from the beam to the column will increase the size of the column. The fact is that the moment is in the column whether it is computed or not. It follows, therefore, that it is in the interest of economy and safety to evaluate this moment as nearly as possible when designing columns. This is an argument against the present practice of designing beams with connections considered as having a rigidity of either infinity or zero.

It is true, as stated, that the more accurate analysis is the more expensive and that the approximate methods will be used in most commercial work. The question that must be solved in each individual case is whether the more correct solution is worth the expense involved.

Mr. Moore has given an entirely different approach to the problem in which he shows that similar investigations are being conducted in aluminum. He introduces the degree of fixity, or the ratio of the bending moment developed in the spliced beam, over the support, to that obtained in a continuous beam. To obtain this ratio he observed the stresses at about eight sections of the beam and computed back to the moment at the connection. This avoided the errors that might have arisen from measuring directly at the connection itself. It is unfortunate that the mathematical equations resulting from this method of attack were not given so that they might be compared with those in the paper, the best in each system being retained.

The tests made by Professor Peck were designed to obtain curves that can be compared directly with those of the paper, furnishing information on the effect of reversal of moment on the connections. The only difference between the tests of Specimens 13 and 14 and those offered by Professor Peck is the ratio between shear and moment. The reason for the change in length of the specimens from those previously used was that the early tests indicated serious deformation in shear before the moment curves had been developed as much as was desired. Although the shear may have some effect on the action of the connection, the writer believes that this question can be approached from a theoretical angle as was done by Professor Batho, but an experimental approach would be very expensive and difficult.

The decrease in the slope of the loading curve, when the connection receives high stresses, is of interest. This is only one of the properties of connections that must be considered when designing a structure. The history of the connections is of necessity a part of the problem of stress analysis. This history is not difficult to anticipate when the frame with its anticipated loads is given.

Tests of the type discussed in the paper are, by their nature, expensive and, therefore, the number cannot be great for financial reasons, although tests are always of value. The writer does not agree with Professor Peck that a long series of laboratory investigations are necessary before the theory can be used in practical design. The question is entirely an economic one.

Sufficient tests have been made so that a general idea of the constants of the connections can be anticipated over the range covered by these tests and even beyond.

It is hoped that the properties of riveted connections will receive further study from the profession because, undoubtedly, they affect the distribution of stress. It is the writer's opinion that the greatest progress can be made by perfecting the method of analysis rather than in increasing the data by laboratory tests. When a method of analysis that is simple and easily applied is devised, it will be accepted by designers. This does not mean that further tests are not of great value but rather that the value of further research in the theory is greater.

Paper No. 1934

HYDRAULIC LABORATORY RESULTS AND THEIR VERIFICATION IN NATURE

By Herbert D. Vogel,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. W. F. Heavey, Chilton A. Wright, Paul S. Reinecke, Morrough P. O'Brien, John A. Jameson, Jr., J. C. Stevens, Paul W. Thompson, Samuel Shulits, and Herbert D. Vogel.

Synopsis

Data contained in this paper were assembled in 1933, added to in January, 1934, and again augmented in the summer of the latter year. Nevertheless, it is quite certain that the intervening months have produced many new facts corroborating the information set forth herein, and while it was not originally intended to present anything like a complete inventory of cases, still it would appear desirable to bring out all new facts in the order of their determination. From this standpoint it would seem that the proper purpose of the paper is to discuss in general the principles of verification of hydraulic model results, to present a number of concrete examples, and to open the way for subsequent discussions. Since the subject can never become closed, it would be presumptious to claim more than a "scratching of the surface" in the present instance. In spite of this, the hope is held that the following pages will serve to assure the profession that efforts are being made to verify the reliability of results obtained by hydraulic model experimentation.

Introduction

What reliance can be placed by field engineers on the solutions obtained from model studies and what proof is there of the statement that a river will re-act to treatment the same as its miniature in a laboratory? These are the questions most frequently asked of those engaged in the task of wresting river secrets from small-scale models, and—strangely enough—they are the

---

Note.—Presented at the meeting of the Waterways Division, New York, N. Y., January 18, 1934, and published in January, 1935, *Proceedings*.

[1] 1st Lieut., Corps of Engrs., U. S. A., 3d Engrs., Schofield Barracks, Honolulu, Hawaii. (Formerly Asst. to Pres., Mississippi River Comm., Vicksburg, Miss.)

most difficult to answer convincingly. Not that insufficient work has been done in laboratories to afford proof of one kind or another, but positive data and positive facts are so few in the general case as to make positive proof next to impossible. It is noteworthy that of the topics assigned for discussion at the XVth International Congress of Navigation (Venice, 1931), one was:

> "The study of hydrotechnical questions by means of laboratory researches on reduced scale models. Comparison of the results of such researches with those of direct observations of the natural phenomena, with a view to ascertaining how far the law of similitude is true", * * *

and that of all the papers submitted only one or two authors showed the hardihood to come down to definite cases of comparison. Furthermore, that German paper which most boldly attacked the subject offered as one of its strongest items of evidence the experiments for determining the spillway discharge of Keokuk Dam, in Iowa, reported in 1929 by Albion Davis and the late Floyd A. Nagler, Members, Am. Soc. C. E.[3] It was shown, as a result of tests on a 1:11 scale model and the actual structure, that there was close agreement between discharge coefficients and other hydraulic functions in model and Nature.

There are many reasons for the difficulties in citing actual instances of complete verification, in Nature, of model findings. Were this not true it would follow either that model tests are entirely unreliable, or that no attempts have been made to present evidence of verifications. The latter assumption having been shown to be in error, and the best authorities having agreed that beneficial results may be obtained from a well conducted model study, it remains to cite a few of the more common reasons for the difficulties that have been encountered.

To begin with, only the more difficult problems are submitted to the laboratory for analysis by experimental means. This is quite natural, of course, since there is no reason for making model studies of problems which present no doubtful elements, or for which there are already satisfactorily established practices. In the second place, most of the problems submitted to the laboratory are accompanied by schedules of detailed proposed plans, each of which is to be tested separately in the model. As a result of the experiment it may be necessary to modify some of the plans in order to find one or more that will produce the desired results. By the time any of these plans has been accepted and instituted in the field it has almost invariably been somewhat further modified to suit the character of changes in local conditions that have taken place in the mean time. Naturally, the difficulty of comparing effects of the work finally installed with those indicated as being most suitable by the model increases with the degree of the modification.

Thirdly, the time required in Nature for structures to become effective differs greatly with the type of the works involved and the character of local conditions. Works, for instance, which are designed to produce changes in the river bed by inducing deposition of silt would be more quickly effective on the heavily silt-laden streams of the West and Southwest than on such comparatively clear rivers as the Ohio, or the Upper Mississippi. If properly located, spur-dikes installed to increase depth of channel at low water by their scouring action, become effective relatively soon in rivers having mud or sand bottoms, whereas in localities in which there are deposits of gravel such dikes may achieve the desired results only at a much later date.

---

[3] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 777.

To obtain the results, in Nature, indicated by a model study, the improvement works should be installed as soon as possible. This is particularly important when the river, or the part involved, is changing actively. In a large alluvial river, such as the Lower Mississippi, delay of one or more working seasons in instituting a plan may be attended by such extensive changes in the river as to affect the success of the proposed plan materially.

In the case of the United States Waterways Experiment Station, experimental work was begun in January, 1931, and the first experiments were not completed until from six months to a year later. A similar period necessarily elapsed before any works, tested during these experiments, could be installed. Consequently, sufficient time has not elapsed to demonstrate conclusive results in every case. However, proofs are not entirely lacking, and a number of cases in which field checks on model results have been obtained, either partly or completely, will be discussed in this paper.

VERIFICATION OF MODEL RESULTS

General.—The present Mississippi River navigation program (adopted January 21, 1927) provides for the procurement of a navigable channel 9 ft deep and 300 ft wide, for all stages of the river, between St. Louis, Mo., and Baton Rouge, La. In this program the principal reliance has been placed on regulatory works, supplemented, where necessary, by channel dredging. Standard practice has been generally followed in the design and location of these works, but in more and more instances, and especially when unusual or baffling conditions are presented, the problems are referred to the U. S. Waterways Experiment Station for study and recommendations.

A technique was quickly evolved for the study of this particular type of problem, because new methods, involving movable-bed models, were required, and special questions, such as those of limiting slopes and of character of sand necessary for the sand bed, required almost immediate answers. Where exigencies of the situation demanded, it was found possible to design and construct a model within less than a month after the receipt of survey data from the field, and to begin the release of experimental data immediately thereafter. This is seldom desirable, however, and with less haste necessary, experiments proceed at a more leisurely pace, some of the studies having been extended for as long as 1½ years.

In certain instances, models have been operated concurrently with the installation of improvement works in the prototype. In such cases, the various construction details, together with any natural changes, have been reproduced as they progressed in Nature, and findings have been forwarded to the field engineers either by mail or by radio.

Field representatives of the various districts for which models have been built are frequent visitors to the Laboratory for the purpose of inspecting the progress of the experiments. Only rarely do these visiting engineers fail to point to some phenomena in the model which are verified by existing conditions in Nature. It may, perhaps, be the formation of a sand bar or a gravel bar, an eddy, a caving bank, or scour in a certain vicinity; or, it may be the development of the general configuration of the bed of the model which bears such a close resemblance to that of the natural reach that it becomes difficult to distinguish between maps of the two. It is noticeable that these engineers nearly always find in the model a simulation of those characteristics of the river with which they are most familiar. This fact lends an added value to such testimonials. Numerous instances are on record in which developments in the natural stream have been predicted from the model studies many months in advance of their actual occurrence.

Hydraulic models have two general functions: First, by their aid a more exhaustive and detailed estimate and evaluation may be made of existing conditions in the prototype, and, as a result of the information thus secured, plans for improvement may be conceived with greater likelihood of effectiveness and economy than would otherwise be possible; and, second, the merit of these plans may then be determined in the model itself. Before a model can be relied upon, confidently, to give such important information, its capacity to simulate known past and present conditions must first be demonstrated. In laboratory parlance, the ascertainment of such facts is termed the "verification of the model".

Theory of Verification.—The first step in the verification of a model is a manual one, that of checking it dimensionally to insure that geometric similarity between the model and the corresponding region in Nature has been obtained. Following this preliminary check, to which every model is subjected, it remains to prove that hydraulic similarity exists, or that results of tests conducted on the model may be used as the basis of designing regulatory works for the full-sized river, harbor, etc. In general, this hydraulic similarity can be verified in any one or all of several manners.

Verification (1).—In the case of a movable-bed model, checks can be made by subjecting it to "moulded-bed" or to "flat-bed" verification runs. If two or more surveys of the vicinity are available, the first method is used. The movable-bed part of the model is moulded to conform to known conditions of the earlier date; the model is subjected to several cycles of flow at varying stages, representing average hydrographs in Nature; it is considered trustworthy only if its capability to reproduce the known conditions of the later date can be demonstrated.

In instances in which field information taken at different dates is not available, the second method is used. The movable-bed part of the model is moulded flat; water is passed through the model at varying stages in simulation of average conditions in Nature; and the test is completed when the model has moulded its bed so that it conforms to the hydrographic conditions in Nature at the time of the survey from which the model was constructed. The reasoning behind such a test lies in the fact that a stream adjusts the configurations of its bed in accordance with its hydraulic regimen and the alignment of its banks. If the dimensional check of the model proves its geometric similarity to the prototype and, if hydraulic similarity exists, the model should mould its own bed in simulation of Nature. All the movable-bed models studied at the U. S. Waterways Experiment Station are subjected to one or the other of these verification tests, and many of them are given both checks.

Verification (2).—The more practical application of this type of check is obtained when a comparison can be made between conditions as they develop in a stream after the completion of a model study and the conditions which the model indicated would develop. This type of field verification can be made in the case of: (*a*) Movable-bed models by comparing bed configurations in streams with the configurations predicted from model studies; (*b*) fixed-bed river models (when it is desired to determine the changes in gauge heights, velocity distributions, etc., resulting from cut-offs or other regulatory work) by a comparison of model predictions with actual developments in Nature; and (*c*) models of spillways, turbines, etc., by similar comparisons.

The work of the U. S. Waterways Experiment Station is too new to have yielded many conclusive verifications of this kind. However, several such comparisons are available, and some of them will be discussed in detail. It should be pointed out that these two types of verifications are fundamentally the same. In each case, a comparison is made between the development of the model and the corresponding development of the prototype. The only difference lies in the time at which the model study is made—whether at the end of the period of development, or at the beginning.

Verification (3).—A third check may be obtained if two or more models to different scales have been used for the study of the same problem. A transference of the results of the small-scale model (by means of the laws of similitude) to the scale of the larger model provides a check on the accuracy of the results of both models. If the two are in fair agreement, it is reasonable to assume the next step in the extrapolation of the model data to the full scale of the prototype. Several examples of each type of verification are described herein.

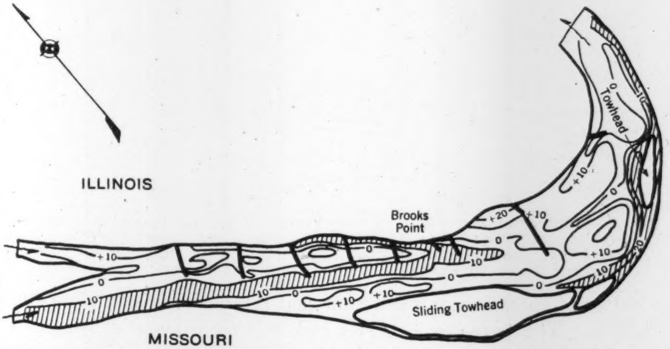

FIG. 1.—CONDITION EXISTING IN NATURE, SEPTEMBER, 1932, IN THE MISSISSIPPI RIVER AT BROOKS POINT, ILL. (CONTOUR ELEVATIONS ARE REFERRED TO LOCAL LOW-WATER PLANE. HATCHED AREAS REPRESENT DEPTHS GREATER THAN 10 FEET).

The Brooks Point Model.—The model of Brooks Point, Ill. (Fig. 1), was built in simulation of a 10-mile stretch of the Mississippi River lying between Mile 20 and Mile 30 above Cairo, Ill. The purpose of the model study was to devise a means for improving the depth of the navigation channel over the crossing at that point during low-water stages. Only one general survey of the region was available to the Laboratory. This was made in September, 1932, and the model was constructed from the data thereof. Fig. 1 shows the conditions in the prototype as revealed by this survey. Lacking any other survey data, the model was subjected to the flat-bed verification test. At the end of 100 hr of operation, it was found that the model was in close similarity with Nature. The map made of its bed at this time is shown in Fig. 2. Attention is invited to the faithfulness with which details in the full scale were simulated by the model.

FIG. 3.—INDICATED SOLUTION, BY LABORATORY TEST, OF CHANNEL IMPROVEMENTS AT BROOKS POINT, ILL. (CONTOUR ELEVATIONS ARE REFERRED TO LOCAL LOW-WATER PLANE. HATCHED AREAS REPRESENT DEPTHS GREATER THAN 10 FEET).

While the experiments on the model of Brooks Point were in progress the Station was visited several times by the engineers in charge of the channel improvement works in the vicinity represented by the model. They were unanimous in voicing their opinion that the model simulated to a marked degree the conditions of Nature.

This model was successful in demonstrating several practicable plans for the improvement of the channel at Brooks Point. One of these, which provided for the construction of five spur-dikes on the right bank just above the shoal crossing, and the removal of three existing dikes on the left bank at a point just opposite, was selected. The details of this plan are shown in Fig. 3. In order to preserve the best conditions for navigation, the removal of the three dikes was conducted concurrently with the construction of the five new dikes. The new dikes were completed in August, 1933, but only sections of the old dikes had been removed at this time. A survey of this vicinity, made about two months later (October, 1933), is shown in Fig. 4. It can be seen that in this short interval of time the river has shown unmistakable signs of adopting the new channel alignment. Fig. 5 is a view of this model with new spur-dikes in place and being tested.

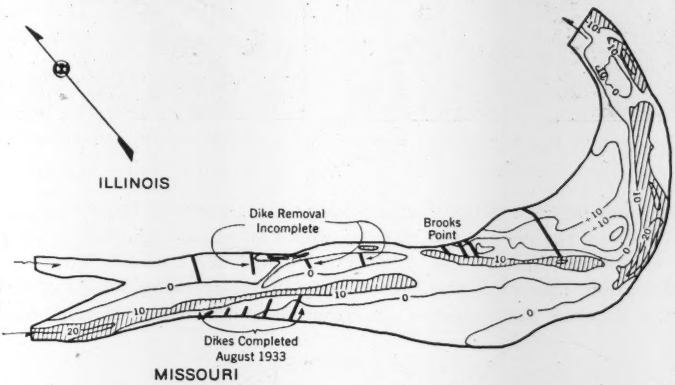

FIG. 4.—CONDITIONS EXISTING AT BROOKS POINT, ILL., OCTOBER, 1933 (CONTOUR ELEVATIONS ARE REFERRED TO LOCAL LOW-WATER PLANE. HATCHED AREAS REPRESENT DEPTHS GREATER THAN 10 FEET).

The Fort Chartres Model.—A problem similar to that at Brooks Point was presented in the case of the study for channel improvements at Fort Chartres, Ill. (see Fig. 6). This model represented that section of the Mississippi River between Miles 120 and 137 above Cairo, Ill. The purpose of the experiment was to determine methods for improving channel depths over the crossing at Fort Chartres, East, situated at about Mile 131. The model was built in accordance with a survey of this region (see Fig. 7) made during October, 1932. The experiment showed that a navigable channel could be procured at low stages if a system of spur-dikes was built on the

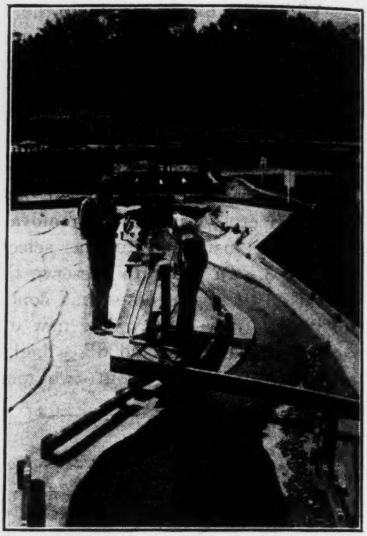

FIG. 6—MEASURING VELOCITIES IN THE FORT CHARTRES MODEL WITH PITOT TUBE AND INCLINED MANOMETER.

right bank between Miles 130 and 133. The details of the proposed system of dikes and the channel which they would effect, as indicated by the model, are shown in Fig. 8. The plan was adopted for construction with slight modification, and work was begun early in the working season of 1933. A survey showing the status of construction and existing channel conditions was made of this region in March, 1934, and is shown in Fig. 9. Although sufficient time has not elapsed for the dikes to become completely effective, it will be noted that they have already caused a relocation of the channel along the desired alignment and that project depths are being obtained along this trace.

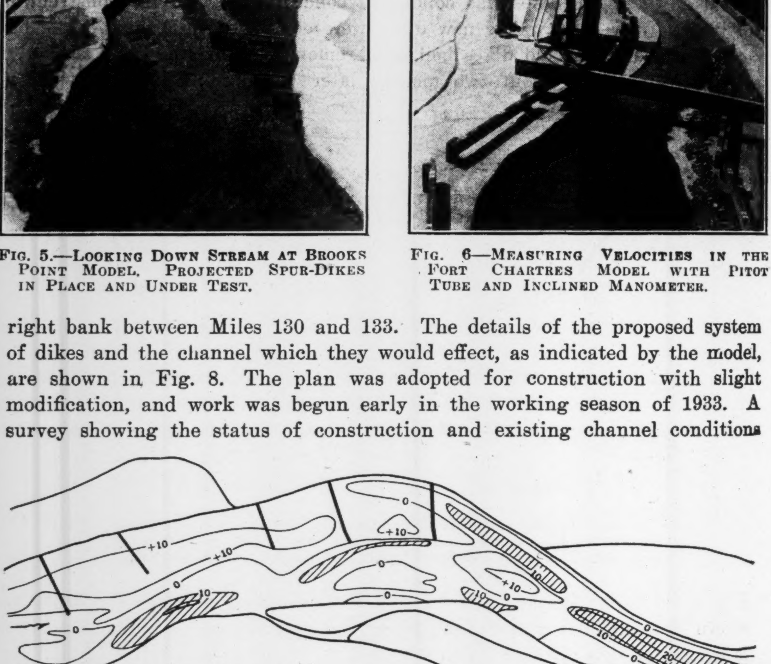

FIG 7.—CONDITION OF RIVER BED AT FORT CHARTRES, ILL., AS SHOWN BY SURVEY OF OCTOBER, 1932.

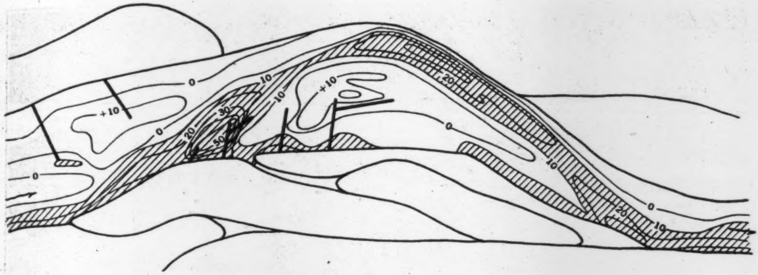

FIG. 8.—PLAN FOR IMPROVEMENT OF CHANNEL AT FORT CHARTRES, ILL., INDICATED BY MODEL TEST.

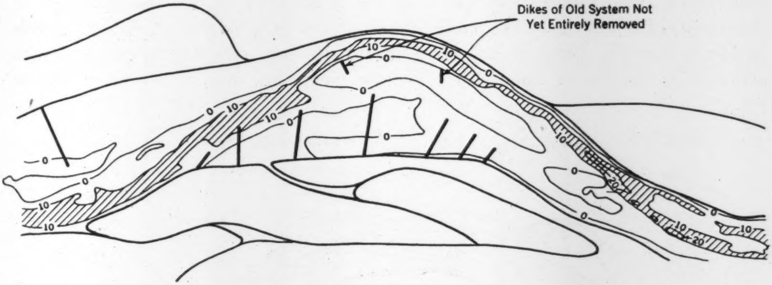
The Point Pleasant Model.—The Point Pleasant (Mo.), reach of the Mississippi River lies about 80 miles below Cairo, Ill. It is one of several localities in which the low-water channel is characterized by excessive width and consequent deficient depth. A system containing three permeable pile-dikes with a combined length of 8 232 lin ft was completed during 1932 for the improvement of depths over the crossing-bar. Surveys made during August, 1932, showed no improvement in the channel depth opposite the dikes and their ability to improve the channel was questioned. Some authorities thought that the dikes should have been placed on the opposite side of the stream, and advocated their removal. At the direction of the President of the Mississippi River Commission, a model was constructed which simulated an 8-mile stretch of the river, extending from Mile 75 to Mile 83, with the Point Pleasant dikes near the center (see Fig. 10). After the model had been properly verified, it was moulded to conform to conditions shown by the latest field survey, which was made during August, 1932 (see Fig. 11). The findings of the model not only substantiated conditions in the field, but indicated that the Point Pleasant dikes were properly designed and located, and eventually would cause the channel to scour to navigable depths (see Fig. 12).



Dikes of Old System Not Yet Entirely Removed

FIG. 9.—PLAN UNDER EXECUTION IN NATURE, CHANNEL AT FORT CHARTRES, ILL., SHOWING CONDITION IN MARCH, 1934.

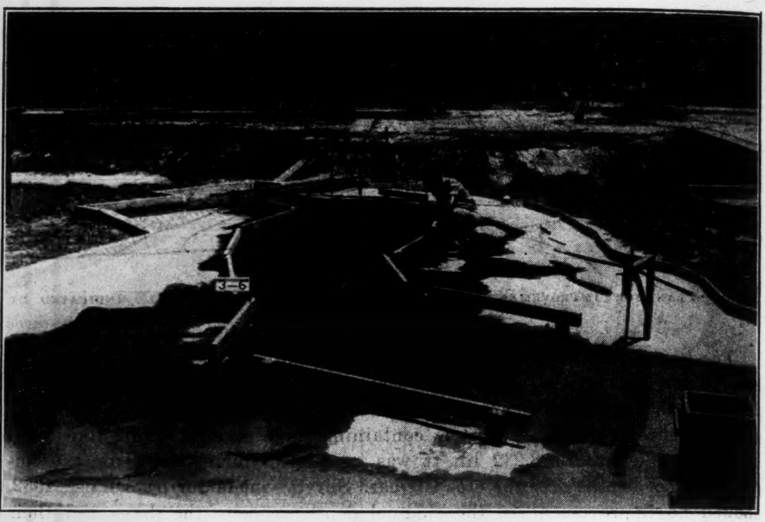


FIG. 10.—VIEW OF POINT PLEASANT MODEL.

Construction of the Point Pleasant model was begun during the first months of 1933, and the experiment was completed before the recession of the annual high water. The model indicated that with the advent of periods of low water the dikes in the river would develop a navigable channel with controlling depths of about 10 ft below mean low water. A survey made by the Area Engineer during July, 1933 (see Fig. 13), showed the crossing-bars to be shaped similarly to those indicated by the model, and revealed depths of 10 ft almost entirely across the critical section. During the next month a continuous channel, 10 ft deep, would probably have developed,

as scouring occurs on the crossings during low water. This would have given a complete verification of the model predictions. In order that there should be no jeopardy to navigation, however, some dredging was done at that time (July). Thereafter, the Area Engineer reported under date of October 27, 1933, that the channel gave no trouble whatever. In fact, as of that date, it had scoured approximately 3 ft. deeper. This was the first time in years, that the crossing was not dredged several times.

FIG. 12.—LABORATORY TEST OF POINT PLEASANT, ILL., MODEL INDICATED EVENTUAL EFFECTIVENESS OF STRUCTURES IN ABOUT ONE YEAR (CONTOUR ELEVATIONS ARE REFERRED TO MEAN LOW-WATER PLANE. HATCHED AREAS REPRESENT DEPTHS GREATER THAN 9 FEET BELOW MEAN LOW-WATER).

Thus, there is—in the foregoing case—an instance in which, through the instrumentality of a model, the eventual effectiveness of existing structures was shown. Such results may be termed "ratifying". The aggregate cost of the Point Pleasant dikes, at an average cost per linear foot of between $30 and $35, was approximately $265 000. Since it is frequently as expensive to remove dikes from a stream as to build them, it would seem that results which lead to such economies are of as great value as those which indicate new plans of attack.

FIG. 13.—CONDITION OF CHANNEL IN POINT PLEASANT REACH, IN JULY, 1933, ELEVEN MONTHS AFTER ORIGINAL SURVEY (CONTOUR INTERVALS ARE REFERRED TO MEAN LOW-WATER PLANE. HATCHED AREAS REPRESENT DEPTHS GREATER THAN 9 FEET BELOW MEAN LOW-WATER).

The Morrison Towhead Model.—Another instance in which a model gave so-called "ratifying" results, is that of the model of the Morrison Towhead. The contraction works program on the Lower Mississippi River provides for the closure, where indicated, of certain secondary or back channels, in order to increase the volume of flow in the main channel during low stages. At Morrison Towhead, 70 miles below Cairo, Ill., it was proposed to block the flow back of the island (Morrison Towhead) by the construction of a single, permeable, deflecting dike at the entrance to the channel.

Before arriving at a decision, however, a model study was undertaken which had for its objective the determination of the proper location for the dike. The model indicated that no bed-load was passing into the back channel and that such deterioration as this channel was experiencing was due entirely to sedimentation which would be retarded by the dike. On the strength of these findings the construction of the dike was omitted. Subsequent surveys were made of the vicinity during May, 1932, and June, 1933. Comparison of these surveys with previously existing conditions affirmed the prior findings of the model.

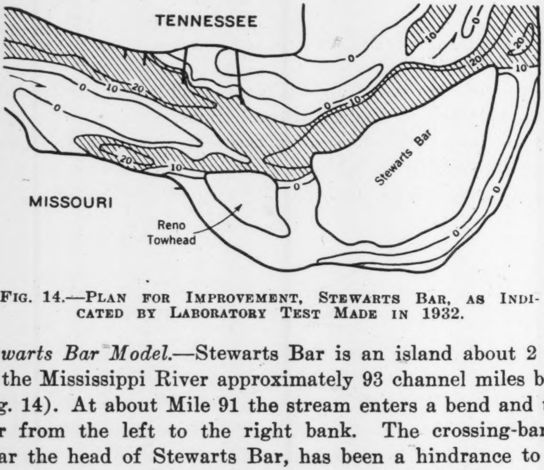

Fig. 14.—Plan for Improvement, Stewarts Bar, as Indicated by Laboratory Test Made in 1932.

The Stewarts Bar Model.—Stewarts Bar is an island about 2 miles long, situated in the Mississippi River approximately 93 channel miles below Cairo, Ill. (see Fig. 14). At about Mile 91 the stream enters a bend and the channel swings over from the left to the right bank. The crossing-bar, which is situated near the head of Stewarts Bar, has been a hindrance to navigation for many years and periodic dredging has been necessary during low stages. Several alternate arrangements of pile-dikes were proposed for the improvement of this reach. The situation was complicated by the fact that over-contraction might re-open the secondary channel behind Reno Towhead and Stewarts Bar and so reduce the flow in the main channel as to cause a deterioration rather than an improvement of navigation conditions. The problem was referred to the Laboratory for study and report.

A movable-bed model, having a horizontal scale of 1:1 000 and a vertical scale of 1:100, was constructed and tests were made during 1932 of each of the proposed plans. In these tests the engineers of the Laboratory considered not only various locations and lengths for the dikes, but dikes of different height and inclination with respect to the flow of the current. A report was rendered which indicated that any one of several of the proposed plans would be effective in producing the desired results.

One of the plans which indicated satisfactory results provided for the construction of four spur-dikes on the left bank between Miles 90.8 and 92.0 (see Fig. 14). With some slight modifications this plan was adopted, approved for construction, and the dikes were completed in December, 1932.

To ascertain what effect the dikes were having, a re-survey was made of the Stewarts Bar Crossing during November, 1933 (see Fig. 15). An examination of the results of this survey shows that the dikes had already secured a channel of the desired depth. Comparing Figs. 14 and 15 a remarkable agreement will be found. In this connection, it should be borne in mind that the full effects of a system of dikes are seldom realized during the first season.

Under date of October 27, 1933, the District U. S. Engineer's Office, at Memphis, Tenn., reported that no dredging was done in this reach during the low-water season, 1933, because, for the first time in years, the channel was in such excellent condition as to cause no concern. The dikes were noted to have been very effective in inducing a heavy fill, and had maintained that crossing at a depth of 10 ft or more all that season, despite extreme low-water conditions.

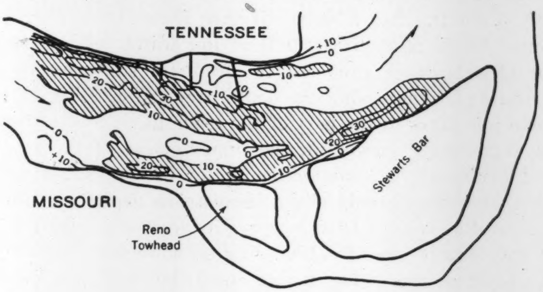

FIG. 15.—CONDITION OF STEWARTS BAR AS SHOWN BY SURVEY OF NOVEMBER, 1933.

The Walkers Bar Model.—The project for the canalization of the Ohio River, from Pittsburgh, Pa., to Cairo, Ill., was completed in 1929. This project was not designed to provide the required depth of 9 ft at all bars, because it was judged more economical to secure the needed depth at the worst crossings by dredging rather than by increasing the height or number of dams. At one location, Walkers Bar, where excessive dredging had been required annually, it was thought that impermeable dikes might provide the required depths more economically.

At the request of the District Engineer of the Louisville, Ky., District, a model study was undertaken to ascertain the feasibility of the plan, and the most effective system of dikes for the improvement of this vicinity. An engineer from the Louisville District familiar with local conditions was detailed to assist in the experiment. The experiment extended over a 17-

month period and was completed in September, 1932. During this time twenty-two separate plans were studied exhaustively and at least two were found which, in the model, gave the desired results.

On May 31, 1934, the U. S. District Engineer Office, at Louisville, reported on an up-to-date survey of Walkers Bar to note the effect of erecting dikes, and the extent of the scour and fill that had occurred since the dikes were put in operation. Benefits to the channel were unquestioned although the survey was made before the end of the high-water season.

The Island No. 9 Model.—For many years deficient depths during the low-water seasons at the Donaldson Point Crossing (Mile 56 below Cairo, Ill.) have proved a hindrance to navigation. In the past it has been the custom to provide relief during low stages by channel dredging. Since the low-water season of 1927, a total of 1 750 000 cu yd of material has been dredged at this crossing. The crossing is situated near the lower end of a reach which, for about 10 miles, lies practically in a straight line. Throughout the greater part of the reach the average width between banks at low stage is approximately 3 000 ft. For a short distance above Donaldson Point Crossing the channel width is about 5 000 ft at low water. The program for the improvement of this reach proposed to eliminate the necessity for annual low-water dredging by increasing the depth over the crossing by constructing four permeable pile-dikes in the part of the reach having excessive widths.

From an engineering viewpoint, the improvement of the reach presented no unusual difficulties. An outstanding factor in connection with the plans was the fact that although only slight increase in depth was desired, a total of 8 500 lin ft of dike seemed necessary to produce the needed results. Hence, the problem was largely one of engineering economics.

After the problem was submitted to the Laboratory, the experiment was conducted with the objective of finding a more economical method of producing the same effect as would be obtained by the proposed 8 500 ft of dike. Several modified plans were found, all of which indicated that the required deepening could be attained at a considerably lower cost than was originally contemplated. The most promising of the several plans indicated that four short pile-dikes on the opposite side of the stream, having combined lengths of only 1 600 ft, built in conjunction with five sand and gravel dikes, would give the required deepening and, at the same time, would furnish protection to the bank in a certain locality where it was being actively caved.

This latter plan, modified somewhat as to physical appearance, but similar as to hydraulic effect, was adopted for field construction, and work was begun in the early part of 1933. A re-survey of the area was made during June, 1933. Although it was too early at this time, of course, to expect that the effects of the works had been accomplished, the survey showed that the structures were tending to produce the desired result although several seasons may be required for its consummation.

Cut-Off Studies.—One of the most excellent opportunities for comparing effects produced by identical changes on similar models of differing scales is that afforded by the experiments designed to determine the results of artificially made cut-offs on the Mississippi River. Among the first models built at the U. S. Waterways Experiment Station was a small replica of the Greenville Bends, its horizontal scale being 1:4 800 and its vertical scale 1:360. With this model, tests were made to determine the effects of all possible cut-offs in the Greenville Bends region.

Some months later a model study was ordered to determine effects of ten dredged cut-offs in the Mississippi River between Rosedale, Miss., and Point Breeze, La. These ten newly proposed cut-offs included two that had been tested by the first model. The second model was built outdoors to scales of 1:2 400 and 1:120, and constitutes, even at this time, the largest model of its kind in the world.

During 1933, two new models were built to a considerably larger scale than had been attempted previously for a study of this kind. These last models, designed to accommodate movable beds of sand, were constructed to a horizontal scale of 1:1 000, and a vertical scale of 1:100. The purpose of their operation was to determine the amount of bed lowering that might be expected up stream from the several cut-offs. Incidentally, water-surface lowerings were also observed in order to check the results previously obtained from the other models. Tables 1 and 2 show comparisons between results obtained from the several models.

Following tests on the 1:2 400 model, certain cut-offs were actually made on the Mississippi River. Subsequent observations have been in line with what would be expected for the current state of development.

HYDRAULIC FLUME TESTS CORROBORATED BY OBSERVATIONS ON RHINE RIVER

Not all cases of similarity between model and prototype are as apparent as the foregoing, but, on the other hand, numerous instances are on record in which experimental data have been checked daily by observed phenomena in Nature. An interesting case of this kind occurred in connection with studies of Island No. 35, up stream from Memphis, Tenn. (see Fig. 16). The U. S. Waterways Experiment Station has a tilting hydraulic flume as a part of its fixed equipment. This flume was used in an extensive series of tests which had as its objective the study of the tractive force of flowing water and the transportation of bed-load material in natural streams. In one phase of the experiments the procedure was as follows: The bottom of the flume was covered to a given depth with sand which had been subjected previously to a mechanical analysis. The inclination of the flume was set to a designated slope, which remained fixed until the completion of the run. Water was then passed through the flume and regulated by means of the weir and the tail-gate so as to have the exact slope of the sand bed. The depth of the water was next increased by successive increments, observations being made and recorded of all essential hydraulic data for each observed depth. Fig. 17 shows in graphic form the results of a typical run. In this diagram depths are plotted as abscissas, and mean velocities, rates of bed-load movement, and experimentally derived values of Manning's *n*, as ordinates.

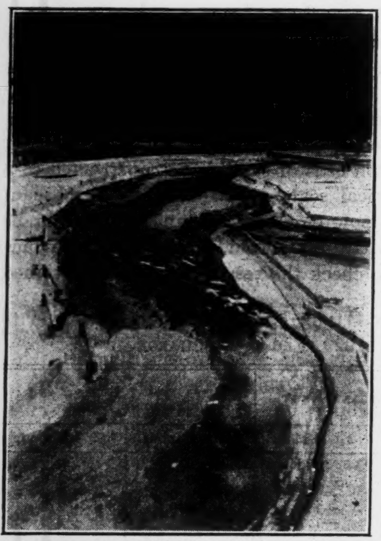

FIG. 16.—MODEL STUDY OF NAVIGATION DIFFICULTIES ENCOUNTERED AT ISLAND No. 35, MISSISSIPPI RIVER.

Several interesting facts were brought to light by this experiment. It was noted that the mean velocity curve broke first at the point where the type of flow changed from laminar to turbulent; the next break in this line occurred simultaneously with the beginning of movement of the bed material. Most authorities are in agreement that when movement of the bed material in a stream begins there is an accompanying reduction in the rate of increase of the mean velocity of the water, with a corresponding change in the roughness coefficient of the stream. This was plainly shown to have occurred in all the foregoing experiments. Although the graphs shown in Fig. 17 are the results of only a single test, several like experiments, in which different sands and different slopes were used, were also performed, and the results were similar in each instance. Fig. 18 is a graph presented by Ph. Forchheimer,[3] which shows data taken on the Rhine River at Basle, Switzerland. The data have been plotted in such a manner that the slope of the curve is a measure of the roughness. The break occurs at the time movement of the river bed begins. In commenting on this graph, Forchheimer states[3] in effect that Kutter knew that the coefficient, *C*, in the Chezy formula decreased when the "geschiebe" (bed-load material), began moving; du Boys, also, was familiar with this fact and mentioned it in his writings; and it is common knowledge among hydraulic engineers that the roughness of a river bed changes as the stage increases.

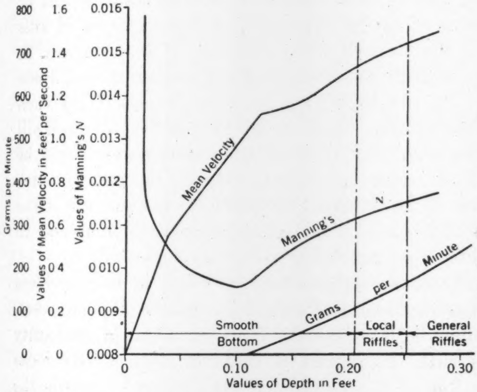

FIG. 17.—HYDRAULIC FLUME TEST OF BED MATERIAL, MISSISSIPPI RIVER, ISLAND 35.

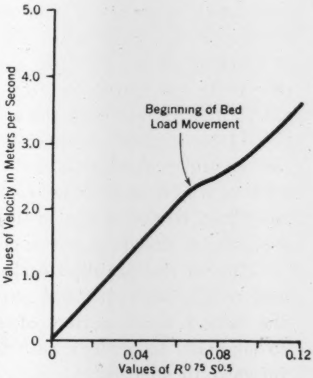

FIG. 18.—RHINE RIVER AT BASLE, SWITZERLAND.

Fig. 18, the result of actual observations, was introduced to show that at the point where bed movement begins there is a change in the variation of the roughness coefficient.

CONCLUSIONS

In the foregoing no attempt has been made to present an inventory of field verifications pertinent to model investigations conducted at the U. S. Waterways Experiment Station. That the list is incomplete is obvious and, in many cases not cited, sufficient similarity has been observed in Nature to compel faith in results of the tests. In some instances verifications have been more difficult—if not altogether too difficult—to obtain. The main point to note is that the science, which was a veritable "infant" only a few years ago is now (1935) a lusty "'youngster", rapidly coming of age, and demanding that its importance be recognized by every one.

DISCUSSION

W. F. HEAVEY,[4] M. AM. SOC. C. E. (by letter).—In 1933, an undistorted model of more than two miles of the St. Clair River, in Michigan, was constructed at the United States Waterways Experiment Station, which is the underlying subject of Lieut. Vogel's paper. The scale of the model was 1:100 and its purpose was to predict the behavior of submerged sills in the St. Clair River, which were proposed to raise the levels of Lakes Michigan and Huron in order to compensate for authorized diversions and for the enlargement of connecting channels. The series of model tests with different types of sills developed the conclusion that the desired compensation of 0.55 ft can be effected by as few as eight submerged sills, instead of the sixteen or seventeen originally estimated in 1926. To obtain maximum effectiveness from each sill it was found, from the model studies, that the up-stream face of each sill should be vertical, or nearly so, and that 60% of its effectiveness would be lost should material be deposited on the up-stream side of the sill to reach its top, which is 30 ft below low-water datum. Fortunately, the section of the St. Clair River at the outlet of Lake Huron carries very little material in suspension, and it is not expected that much fill will be so deposited.

Due to the peculiar difficulty of a mathematical solution to this problem and to the accurate and extensive data available for comparative purposes, the actual construction of these sills will afford an excellent opportunity to compare laboratory results with the action of Nature. The writer looks forward to successful vindication of the laboratory results, and hazards the prediction that not more than six sills will be required. Present plans are to construct only two sills as the first step and to observe the results obtained therefrom before constructing additional sills.

In 1929 a new concrete caisson breakwater at Milwaukee, Wis., was damaged by a severe storm. At that time, there were several theories as to the reason for the failure. Apparently, it had failed because of scour on the harbor side, which had been thoroughly riprapped only a few weeks before the storm, but with smaller stones than had been used on the lake side.

A model of a small section of the breakwater on a scale of 1:24 was constructed in an indoor tank, 4 ft wide by 10 ft long by 3½ ft deep. Small flux stone was crushed to scale and a device for creating waves corresponding to natural waves 20 ft high was installed. A cross-sectional view of the breakwater with rip-rap on both sides was available through a glass window in the side of the tank. As the size of the wave increased, it was observed that the drag of the receding wave and the waterfall action of the wave spilling over the breakwater were working stones loose on the harbor side, moving them back and forth until they were rolled some distance from the breakwater. After 60 hours of continuous wearing down of the rip-rap on the harbor side, the model breakwater suddenly failed. The larger sized rip-rap on the lake side was undamaged. This and subsequent experiments with larger rip-rap proved conclusively that, contrary to popular belief, heavy well-placed rip-rap is as essential on the harbor side as on the so-called "exposed" side of a breakwater in all cases where waves spill over the breakwater.

---

[4] Major, Corps of Engrs., U. S. Army; Chf., Personnel Section, U. S. War Dept., Washington, D. C. Major Heavey resigned his membership on December 31, 1935.

These examples are cited in support of the author's contention that model experiments may be profitably used in "verification" of the action of Nature, as well as in foretelling what the action of Nature will be on work not yet undertaken.

Chilton A. Wright,[5] Assoc. M. Am. Soc. C. E. (by letter).—Field verification of the results obtained from model tests of hydraulic structures and rivers in several instances in which mobile sand beds were used in the models, is the basis of this excellent paper. Observations and surveys in the field yielded a good check as to the main features of the bed configuration and of the water stages developed in the model.

The present interest in the possibility of predicting from model tests the effects of control works on actual rivers impels the writer to cite an instance observed in Sweden in the summer of 1933. The regulating gates of the dam at the new low-head hydro-electric plant at Vargön are to be used to regulate the weekly flow of the Göta River at Lake Vänner, a natural lake about 2140 sq miles in area.[6] The discharge of the river varies up to 30 000 cu ft per sec, the up-stream water level varies by 13 ft, and the down-stream level by 4.3 ft. These facts preclude the use of the usual discharge formulas.

The problem was taken to the Hydraulic Laboratory of the Royal Technical University, at Stockholm, where models of various types of sector gates were constructed in the hydraulic flume at a scale of 1:25, in order to determine the discharge as a function of the up-stream and down-stream depths and the gate-opening. Another model study of the entire project was made later at a scale of 1:36, in order to determine the interrelation of the discharges through the various gates and turbines.

The discharge diagrams obtained from the laboratory tests were compared with an official discharge curve developed previously for the Göta River from current meter measurements, and the diagrams showed a deviation of only −2% from the model results. A new set of discharge measurements was made at the weir in 1932 by means of a current meter, during a period of comparatively low water. No variation from the discharge curves based on the model tests could be observed over the range of these measurements.

This example corroborates the evidence given by Lieut. Vogel that in many cases the actual performance of hydraulic structures built according to designs determined by means of model studies in a laboratory can be predicted from these tests with a high degree of accuracy. Although the bed of the model was fixed in the case cited, rather than built of sand, as in the tests which Lieut. Vogel reports, the results obtained will be of equal interest.

[6] "Untersuchungen betreffend die Abflussverhältnisse an Regulierwehr bei Vargön für die Wochenregulierung des Gota Älv," by Wolmar Fellenis and Erik G. W. Lindquist, M. Am. Soc. C. E., Meddelande från Vattenbyggnadsinstitutionen vid Kungl. Tekniska Högskolan, Stockholm, Sweden, No. 7, June 1933.

PAUL S. REINECKE,[7] M. AM. SOC. C. E. (by letter).—The tests applied at the U. S. Waterways Experiment Station, at Vicksburg, Miss., to "prove" the correctness of a solution are described, clearly and concisely, in the paper. The "tests" are simple, understandable, and reasonable even to those who are not laboratory experts.

One reason why the solutions have been so uniformly satisfactory is that not only were visitors from the field invited to witness the tests, as explained by the author, but in the early three years of the Station's history (and the writer believes the custom is still being continued), it was obligatory for a field engineer, familiar with conditions at the site of the proposed improvements, to be present at the laboratory at least during the crucial periods of the test and preferably throughout the testing period. For this reason "theoretical" results were carefully "tied in" at all times with existing conditions and with practical results. Such a requirement prevented much waste motion in following a line of research which could not prove practical on account of field conditions that were not consonant with the theoretical assumptions made.

During the first few years after the establishment of the Waterways Experiment Station its personnel necessarily worked under a severe strain. Congress had adopted the Flood Control Plan which had to be set in motion promptly in order to avoid the danger of damage from another great flood. (So great was the early progress made that, in 1929, after less than one year's work, the repaired and improved Mississippi River levees withstood, without a single break, a flood equal to, or greater than, any previous flood in the river's leveed history, excepting only the Great Flood of 1927—a hitherto unprecedented record.) Consequently, it was necessary to have reasonable answers for the details of "location" problems long before the laboratory could build up a well-trained staff or develop a thoroughly tested method of procedure. The only alternative was for the U. S. District Engineers in the Mississippi Valley to proceed along lines previously laid down and found reasonable, without any benefit of model study. In fact, it was necessary to proceed with considerable work before laboratory solutions were available and, naturally, in some few cases errors of judgment were made. For instance, training dikes were placed in several locations where satisfactory results were not obtained. Here, again, the Experiment Station came to the rescue of the country's pocketbook. Instead of scrapping these expensive completed works—costing more than $100 000, and building a new set elsewhere at similar expense—the laboratory solution indicated how a relatively slight modification of the existing system could be made to produce satisfactory river conditions. In this regard, it must be borne in mind that, in the present state of knowledge, the hydraulics—especially of stream flow—the construction, and the location of improvement works still involve more art than science, and, consequently, there may be more than one "satisfactory" manner of improving any certain reach of river.

---

[7] Major, Corps of Engrs., U. S. A.; U. S. Dist. Engr., St. Louis, Mo. (Formerly Asst. to President, Mississippi River Comm., in Chg. of Operations and Planning, Vicksburg, Miss.).

With the assistance that model study was able to give, it was possible to avoid repeating the failures of approximately 50 yr ago in locating contraction or training works in the Lower Mississippi, where the great force and changing direction of the attack of the current during the varied changes of river conditions between high and low waters, exert such terrific strains on river structures. Due partly to their location and partly to their method of construction, the dikes and dams built in the Plum Point (Tenn.) Reach in 1881–85 were uniformly disappointing in permanent results obtained. The laboratory solution of the problems in this same reach bids fair to assist in improving permanently a troublesome stretch of river.

Model study, verified by the tests indicated by Lieut. Vogel, affords a reasonable answer, not only of the question as to where to build, but also of the question whether to build at all—as witness the problem at Morrison Towhead, below Cairo, Ill. Before the results of model study were available for this site, there was considerable argument whether the closing dike should be built at the head of the back channel or chute, at its foot, or near the middle. Many "pet ideas" were put forth, with the usual chance that the longest winded and loudest protagonist among all concerned would finally win. However, the results of trying out the different ideas in a model indicated quite apparently that the best answer was to let Nature alone at this place and save the Government's money.

In his remarks concerning studies on the Island No. 9 Model, Lieut. Vogel touches on the question of costs. The quoted figures indicate an average of about 30 000 cu yd dredged annually during the preceding 6 or 7 yr. At a cost of 5 cts per yd, the annual charges amount to $1 500 per yr (disregarding expense of delays to navigation). The original plan of contraction works (8 500 lin ft at $35 per ft) would cost about $297 500, and the annual carrying charges at 5% for maintenance until the dikes have been silted in permanently, and for interest, would be nearly $15 000 per yr—or ten times the cost of dredging. The approved solution of the laboratory, requiring only 1 600 lin ft of dikes, would cost only $1 600 to $1 700 annually. Consequently, in comparing the annual cost of the dikes with the cost of dredging, plus the expense to shipping on account of the delays, it is obvious that the improvement of the river by contraction and training works is warranted at this locality.

The foregoing analysis should help answer the question as to whether the building of contraction works in the Lower Mississippi is a waste of public funds, as some "dredging only" enthusiasts maintain. These latter do not in the writer's opinion give sufficient consideration to the extra expense caused by delays in transit while waiting for dredges to open up channels through numerous sand-bars developed after every high water. If it is possible, at reasonable cost, to contract and train the river to scour out these bars as the waters subside, and thus do away with the necessity of so many dredges, then by all means such training works should be constructed and the delays in transit due to shoal waters avoided. The laboratory affords a cheap and satisfactory method of estimating the efficiency and necessary length of training structures, and, consequently, their cost, to compare with the average cost of dredging in the same reach of river in its unimproved condition.

Very properly, Lieut. Vogel insists that any problem assigned for laboratory study must be assigned "without strings." A laboratory is a good and inexpensive place to try out "hobbies," provided it is not limited in experimentation only to those hobbies. Every possible and reasonable solution must be investigated, and the best ones recommended. In the early years of the Station (and also since as far as the writer knows personally) the Station Director was never limited to only one or two preconceived answers, but was urged and directed to get the best answer possible. The high type of engineering-scientific personnel on duty at the U. S. Waterways Experiment Station fully entitles them to the confidence placed in them.

MORROUGH P. O'BRIEN,[8] ASSOC. M. AM. SOC. C. E. (by letter).—The importance of verifying the results of river model experiments by comparisons with Nature is emphasized in this paper. One criticism that may be offered is that the comparisons presented are restricted to river models, whereas the author implies in the "Introduction" that hydraulic models generally are being examined.

While he was a student in Germany, the writer was struck by the fact that, although great reliance was placed on model experiments of all kinds, few quantitative comparisons of models with Nature had been published. In "Hydraulic Laboratory Practice,"[9] which was a review of model theory and results, almost no such verifications are to be found. In France, England, and the United States, the question of the reliability of models has been given more attention. An elaborate comparison of models of different sizes has been made in a paper by Carmichel and Escande.[10] This study covered the following subjects: Weirs, orifices, and tubes; uniform flow in open channels; transportation of steel spheres; surfaces of discontinuity behind obstructions; vortices, whirlpools, and gyrating motions; spillways and intakes; and flow in pipes at high velocities. In general, these experiments showed a scale effect that was not great. Carmichel and Escande also presented a complete and concise survey of model laws.

Concerning models of movable river beds and estuaries, Osborne Reynolds and Vernon-Harcourt felt the need for careful studies of the reliability of their results, but later experimenters have not always been as cautious. As to results obtained, Reynolds stated that, after a long period of operation, his model resembled the estuary of the Mersey River as well as charts, made at different times, resembled each other.

In the model of the Severn Estuary,[11] Professor A. H. Gibson investigated the discrepancy between results obtained with different vertical scales and different sands, and also compared his model with Nature. The scales finally adopted were 1: 8 500 horizontally and 1: 200 vertically, with a model sand size of 0.007 in. as compared with an average size of 0.009 in. Professor Gibson stated that these models reproduced, with a high degree of accuracy, the behavior of the tides at all points in the estuary, both as regards their height, range, and rate of rise and fall. Furthermore, the phenomenon of the bore was also reproduced with a very close agreement between the height and speed as measured in the model and as observed in the estuary. Observations of the drift of floats, and of current velocities at various points above and below the English Stones, he reported, agreed well with those at corresponding points in the estuary. Generally, all the phenomena connected with the movement of the water in the estuary were reproduced with a remarkable degree of accuracy in the model.

[10] XVth International Congress of Applied Mechanics, Venice, 1931.

[11] "Construction and Operation of a Tidal Model of the Severn Estuary," H. M. Stationery Office, London, 1933.

A comparison of the charts and cross-sections of the sand banks, silt deposits, and the main channels that were prepared from surveys of the model at times corresponding to 1886, 1901, and 1924, with corresponding charts and cross-sections of the estuary itself, showed a good general agreement over at least 90% of the area of the estuary. According to Professor Gibson, this agreement was as close as could be expected,

> "In view of the fact that the model was not exposed to the effect of storms, which are liable to produce relatively large changes in any natural estuary. While there are differences in detail, these are not so great as the corresponding differences in detail in the estuary itself at the times of the different surveys. The only points of marked difference occur where, owing to some rapid deepening of the bed of the estuary, the slope of its sand banks is so great that the angle of repose of the sand in the model would have to be exceeded in order to give accurate reproduction."

The changes in the mean level of this estuary were reproduced with considerable accuracy in the model, and, generally, the agreement was bound to be such as to justify the assumption that "changes similar to those produced in the model by the introduction of a barrage would also be reproduced under similar conditions in the estuary."

For some time, the staff of the Hydraulic Laboratory at the University of California has been investigating the correspondence between models and prototypes. A few of the experimental results obtained by students have been published by the writer.[13] Additional work has been done by A. W. Kidder, Assoc. M. Am. Soc. C. E., the late John A. Jameson, Jr., Jun. Am. Soc. C. E., and others, and this work is being continued.

The discussion by Mr Jameson, published herewith, was prepared before his death to serve as his contribution to the data which Lieut. Vogel has offered in various papers. Its application to the present paper by Lieut. Vogel will be apparent from the content.

As would be expected, agreement between model and prototype is best when the reduction in size is not great and when the absolute depths and velocities considerably exceed certain critical values depending upon viscosity and surface tension. Furthermore, phenomena, such as flow over spillways, in which changes in pressure, momentum, and elevation are large as compared with the forces of friction, can be represented in models more faithfully than those in which friction is a dominant factor, as in models of rivers. In addition to the errors resulting from incorrect reproduction of the friction forces in fixed-bed models, river models having movable beds suffer from a lack of information on bed movement sufficient for the formulation of a proper model law. The author's comparisons of models and Nature show that in Nature there is a tendency toward the conditions found in the model, but on the basis of the data presented, one should not conclude that quantitative correspondence may be expected.

---

[13] "Checks on the Model Law for Hydraulic Structures," *Transactions*, Am. Geophysical Union, 1932.

JOHN A. JAMESON, JR.,[13] JUN. AM. SOC. C. E. (by letter).—For the past few months (1934) the writer has been engaged, at the Hydraulic Laboratory of the University of California, in a systematic study of the limits of hydraulic model correspondence, in the course of which certain observations have been made, which may be of interest.

True Models.—A model (scale 1:20) has been built of a concrete-lined tunnel conduit with its inlet and outlet transition connections to a concrete flume. In operating this model the elevation of the water surface in the flume below the outlet transition was controlled so as to correspond to that observed in tests[14] made on the prototype and the discharge for the model, Q_m, was adjusted according to the relation, $q = l^{\frac{5}{2}}$, or,

$$Q_m = \frac{Q_n}{1\,790} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(1)$$

[in which q = the scale ratio of discharge, $\frac{Q_m}{Q_n}$; l = the scale ratio of length; Q_m = discharge through the model; and, Q_n = discharge through the prototype.]

Photographs of the prototype show a fish-tail wave in the outlet transition, which closely resembles that observed in the model. In Nature, fish-tail waves were observed at the outlet from the tunnel and a similar phenomenon occurred in the model.

Flow in the tunnel section of the model was characterized by standing waves. The first of these waves which occurred just below the tunnel entrance, had a height of about 15% of the water depth, while down stream the wave height decreased progressively. According to the observers who conducted the test on the prototype, no waves were observed when sighting through the tunnel, the flow being smooth. The possible reasons for their appearance in the model are: (1) The proximity of the depth of flow to the critical point; (2) the impossibility of obtaining correspondence of friction factors between the model and the prototype; and (3) the shortness of the approach channel.

---

[13] Research Asst. in Mech. Eng., Univ. of California, Berkeley, Calif. Mr. Jameson died September 26, 1934.

[14] Data presented to the Special Committee on Irrigation Hydraulics by Fred C. Scobey, M. Am. Soc. C. E. (Unpublished).

Using the observed field data for the points at the ends of the tunnel, the value of Manning's n was found to be 0.0105. In a previous paper,[15] the author derives from the Manning formula the relation, $q = \frac{a^{\frac{5}{3}}\, s^{\frac{1}{2}}}{n\, p^{\frac{2}{3}}}$, or,

$$n = \frac{a^{\frac{5}{3}}\, s^{\frac{1}{2}}}{p^{\frac{2}{3}}\, q} \dots\dots\dots\dots (2)$$

[in which a = a scale ratio for areas, $\frac{A_m}{A_n}$; s = a scale ratio for slope, $\frac{S_m}{S_n}$; n = a scale ratio for roughness coefficient; and, p = a scale ratio for wetted perimeters, $\frac{P_m}{P_n}$.]

Since $a = l^2$, $s = 1$, $p = l$, and $q = l^{\frac{5}{2}}$, Equation (2) yields,

$$n = l^{\frac{1}{6}} \dots\dots\dots\dots (3)$$

For the model in question, $l = 20$ and $n = (20)^{\frac{1}{6}} = 1.65$, so that N_m for the model should be $\frac{0.0105}{1.65} = 0.00635$, in order to satisfy the foregoing relations. Actually, N_m was found to average about 0.0081 when computed from measured data for the same two points considered in the prototype computation.

The shortness of the approach section between the forebay and the model proper and the rather sudden transition from the forebay supply tank to the channel were necessary because of limitation of space. It was impossible to make the approach longer than about 18 in. (or about six times the depth of flow), and this condition resulted in undesirable turbulence in the flume approaching the tunnel. Several different types of baffles were investigated, but none seemed to have an appreciable effect on the standing waves in the tunnel, which may indicate that the latter were not caused by the shortness of the approach section.

When the results of the model tests are transferred to the prototype, the forebay level is about 10% higher in the model than in the prototype for the same discharge and down-stream water-surface elevation.

Distorted Models.—The distorted models included three open channels of rectangular section lined with painted galvanized iron, each consisting of two tangents connected by a 90° elliptical bend. These channels were the same depth (6 in.), but their horizontal dimensions were in the ratio of 1:2:4 (that is, considering the 12-in. channel as the prototype, the 6-in, and the 3-in. channels had horizontal scale ratios of 2 and 4, respectively). The bottoms of all three channels were horizontal and all opened into a large forebay tank at the upper end and discharged into a return channel at the lower end. In these tests each channel entrance was fitted with a galvanized-iron transition section to smooth out entrance eddies, and each had a galvanized-iron sharp-crested weir at both entrance and exit to isolate the section of the channel being studied from disturbance up stream or down stream. The entrance weirs operated in a submerged condition and their crests were fixed at the same elevation (about 2.5 in. above the channel bottoms). When the channels were calibrated individually it was found that the discharges were nearly in the ratio 1:2:4 (the quantity per foot of weir crest being: 12-in., 0.230 cu ft per sec; 6-in., 0.234 cu ft per sec; and, 3-in., 0.232 cu ft per sec. for a head on the weirs of 0.166 ft).

---

[15] "River Laboratory Hydraulics", *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 118.

With water flowing through the channels sand was introduced into each immediately below the upper weir, the weights of sand being proportioned to the squares of the horizontal scales (that is, 1:4:16). When the water was shut off, and the channels were drained, it was observed that there was a definite line in the two larger channels above which there was no deposition whatever, due to the scouring action of the water below the entrance weirs. This line was parallel to that of the entrance weirs and not at proportional distances down stream as would be expected in scale models. In other words, the horizontal dimensions are controlled by the vertical, and distortion is not permissible. This condition also existed in model tests for the Hastings Dam, where a distorted model was used to study scour below gates.[16] The same line of scour would undoubtedly have appeared in the 3-in. channel if there had been longer tangent sections before the bends. As it was, the scour line for the two larger channels intersected the small channel in the curved part of its length so that no definite line appeared, although no sand remained in the up-stream tangent section.

Another factor that must be considered in using distorted models for experiments with bed load is the effect upon friction coefficients of the different proportions of bottom and sides making up the wetted perimeter in the model and prototype. In another series of tests, the entrance weirs were removed, and the lower weirs adjusted to compensate for the aforementioned friction differences. This was accomplished by raising the weir crests in the two smaller channels by computed amounts so that the slope of the water surface and the mean velocity would be approximately the same for all three channels. Wooden spur-dikes, 1 in. high, were placed radially at corresponding locations in the three channels, and the entire bottom of each channel was covered with about 0.4 in. of sand. The water passed through the channels at a depth of about 0.34 ft and at a velocity just sufficient for sand movement. The times of flow were in the ratio of 1:2:4. Although there was qualitative correspondence, it was observed that in spite of the fact that the weirs were adjusted carefully, so as to give equal mean velocities, the scour in the 3-in channel was more rapid than in the other channels.

J. C. STEVENS,[17] M. AM. SOC. C. E. (by letter).—"Man marks when he hits but fails to mark when he misses." The author has given some excellent examples confirming the behavior of open river models by prototype performances. It is truly remarkable that the small-scale models and distortions between horizontal and vertical dimensions which it was necessary to adopt, should show such excellent similitude of behavior, and this is all the more remarkable when one realizes that the model sands could not have differed greatly from the prototype sands. To reduce sizes of model sands to simulate prototype sands is impossible, of course. If it were done the model material would be colloidal.

---

[16] "Laboratory Tests on Hydraulic Models of the Hastings Dam," *Bulletin No. 2*, Univ. of Iowa Studies in Engineering.

[17] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

It would have been most instructive if the author could have drawn from his magic bag an example or two in which prototype performance failed to conform to model behavior, and explained the "why" of the failure. It is vitally important to be able to recognize the limitations of models and to stay within those limits. Failures are the most potent means of defining those limitations. The writer, therefore, offers the following negative "verification" with the belief that it will be just as instructive as the author's positive ones.

Field tests of three of the seven Leaburg siphons were made by the writer, and the results have been fully described.[18] Three models of Siphon No. 7, to scales of 1:20, 1:15, and 2:15, had been made and tested independently, and a study of the published[19] results will reveal the following points of dissimilarity between model and prototype performances:

1.—It was impossible to simulate the cavitation effects found in the prototype. Velocities practically corresponding to a head of 1 atmosphere were found in the Leaburg siphons near the summits. The live stream passing around the summit curves would swing from one side of the barrel to the other, leaving the intermediate spaces filled with pronounced eddies at high negative pressures.

In the model the live stream completely filled the barrel of the three models, and no effect of cavitation was detected.

2.—The coefficients of discharge for the models were higher than for the prototype. Based on the outlet area of the siphon the coefficients of flow,

$$C = \frac{Q}{A\sqrt{2\,g\,H}}, \text{ were:}$$

Models	Coefficient of Flow	Percentage Error of Model
Prototype, No. 7 Siphon	0.63	....
1:20 model	0.68	+ 8.0
1:15 model	0.69	+ 9.5
2:15 model	0.71	+12.7

The models showed consistently higher discharges than the prototype, and the larger the model the greater the error. This is believed to be due to the eddy losses in the prototype as a result of cavitation that did not exist in the model.

3.—The depth of flow on the crest of the siphon summit necessary for priming was much less in the prototype than in the model. At first, this was attributed to air leakage around the priming gates of the prototype. In the models, as the forebay rose air was compressed in the summit which precluded the possibility of obtaining sufficient depth of flow over the crest to prime quickly.

---

[18] "On the Behavior of Siphons," by J. C. Stevens, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 986.

[19] *Transactions*, Am. Soc. C. E. Vol. 99 (1934), p. 1008; also, *Engineering News-Record*, August 18, 1932, p. 187.

A small air outlet at the summit of the 2:15 model was provided to simulate the air leakage at the summit of the prototype which improved somewhat the sensitiveness to priming of the model. The question arose: If the leakage around the primer of the prototype were stopped would it require a greater depth of flow to prime? In order to test this, the priming gates of all three siphons were later sealed tightly and tested for priming head. The siphons became more sensitive and primed with less depth of flow than before sealing the gates, as the following will show:

Head Required to Prime, in Feet	Siphon No. 7	Siphon No. 6
Primer unsealed	0.41	0.34
After sealing primer	0.19	0.20

The explanation of why the siphon models failed in these important particulars to predict prototype performances probably lies in the fact that the tests were based on the Froudian similitude for gravity forces, whereas friction forces, including eddies and impact, have effects of nearly equal magnitude in producing the phenomenon of flow through them. These friction forces become of great importance in the prototype on account of the high velocities, but are of lesser moment in model performance because of the relatively low velocities that obtain in them.

Paul W. Thompson,[20] Jun. Am. Soc. C. E. (by letter).—The author "hits a nail on the head" when he refers to the infrequency of the cases in which actual recorded data from a prototype have checked data previously secured from a small-scale model of that prototype. His paper presents the results of what is probably the most extensive, and successful, attempt yet made to confirm model results by actual data from the prototype.

It appears that the illustrations of the paper offer almost conclusive proof to the proposition that small-scale models are capable of yielding dependable qualitative data, even in the cases of problems involving erosion and transportation of débris by rivers. It might even appear from the illustrations that quantitative results have been obtained from the models; however, such appearance is probably coincidental rather than real. There are a few stubborn facts, each of which seems to preclude the possibility of any precise quantitative interpretation of data derived from small-scale models, at least in so far as problems in erosion and transportation of débris are concerned.

To begin with, he who would study problems involving the transportation of débris in natural rivers is confronted by a phenomenon about which little is known. It would not appear to be possible to simulate exactly a phenomenon when the phenomenon itself is imperfectly understood.

---

[20] Lieut., Corps of Engrs., U. S. Army; Care, Military Atttaché American Embassy, Berlin, Germany. (Formerly Asst. to Director, U. S. Waterways Experiment Station, Vicksburg, Miss.)

The troubles of the experimenter are not confined to the difficulty of attempting to simulate characteristics about which he knows little. Frequently, he finds himself unable to simulate those factors about which he does know something. Thus, most of the models described by the author were built to a horizontal scale of 1 to 1 000 and to a vertical scale of 1 to 100. Such distortion of linear dimensions was necessary and, as the results of the experiments show, was justified. However, there is no question but that distortion affects the behavior in a model. Just what the effects may be seems to be beyond accurate determination at the present time; but it does appear unreasonable to believe that a model which is geometrically similar to a river ten times as deep as the one being investigated, can yield precise quantitative results in regard to the latter.

The fact that data from small-scale models are often not quantitatively dependable should cause no one to conclude that model studies are a waste of time and money. That carefully designed models are capable of yielding data which are qualitatively and comparatively dependable is enough to justify the use of such models in almost any problem in hydraulics involving large expenditures of money. Perhaps a time will come when models which produce quantitative results can be built; however, by that time science will probably know all the answers that the models can give. Meanwhile, the Engineering Profession is indebteded to Lieut. Vogel for another convincing presentation of the possibilities of model research.

SAMUEL SHULITS,[21] JUN. AM. SOC. C. E. (by letter).—In a convincing manner, Captain Vogel presents the practical value and qualitative reliability of river models. However, it is the problem of the quantitative evaluation of fluvial models that confronts laboratories everywhere to-day and further systematic research is necessary to clarify this phase of river-model usefulness. At present, the writer is inclined to agree with Koerner[22] that the results of properly planned experiments with movable-bed models are always qualitatively transferable to the prototype in Nature. In other words, it is always determinable which of the investigated construction measures promises the greatest efficacy in the desired direction. According to Koerner, it is still necessary, however, to exercise great care in applying quantitative conclusions derived from river-model studies to predict the behavior of prototypes.

Although the path may be difficult, there is gratifying evidence that movable-bed models can yield quantitative results. For example, the Schoklitsch bed-load formula[23] was developed rationally, its constants were determined in a laboratory flume, and the results have been found to hold for several European rivers. It correlates bed load, size of material moved, energy gradient, and discharge.

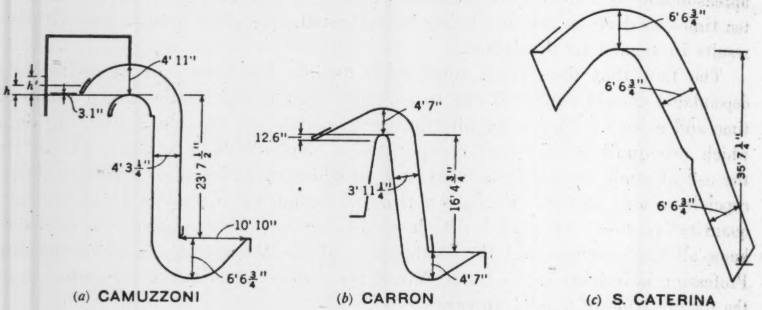
[21] Asst. Engr., U. S. Bureau of Reclamation, Denver, Colo.

[22] "Modellversuche für einen Fluss mit starker Geschiebebewegung ohne erkennbare Bankwanderung", by H. D. Krey, prepared and edited by Burghard Koerner, Berlin, 1935, p. 38.

[23] "Der Geschiebetrieb und die Geschiebefracht", by A. Schoklitsch, *Wasserkraft und Wasserwirtschaft*, No. 4, 1934, p. 37; also "The Schoklitsch Bed-Load Formula" by Samuel Shulits, *Engineering*, June 21 and 28, 1935, pp. 644 and 687.

Furthermore, it has actually been possible to find an accurate quantitative relation between the discharge, the head, the size of the bed material, and the pool depth below a jet falling freely over a sharp-crested weir[24] in a small model. In this case, eight different sands of non-uniform composition were used. To be sure, some may say that the relation thus obtained is valid only for the small model, but it must be realized that the search for even such a relationship was considered futile not long ago.

Lack of agreement between siphons and their models has been reported by A. Veronese.[25] Three models, of different scales, were made of siphons (Fig. 19) in Italy; the purpose of the tests was to determine the relationship between the minimum head (*h*, in Fig. 19), and the corresponding time, *T*, required to prime, in both model and prototype. If the subscripts, *m* and *n*, denote, respectively, model and prototype, and if the scale ratio is expressed as 1 : *a*, then, with Froude's law as a basis, the relations between priming head and priming time should be:



(*a*) CAMUZZONI (*b*) CARRON (*c*) S. CATERINA

FIG. 19.—SIPHONS INVESTIGATED BY ALESSANDRO VERONESE.

$$h_n = a\, h_m \qquad (4)$$

and,

$$T_n = T_m \sqrt{a} \qquad (5)$$

but Veronese's experiments led him to conclude that Equations (4) and (5) are invalid, and he derived the following from the data:

$$h_n = h_m\, a^b \qquad (6)$$

and,

$$T_n = \frac{T_m}{\sqrt{a}} \qquad (7)$$

in which $b = \dfrac{24 \sqrt{a}}{T_m}$. The agreement (which can be termed sufficient, per-

haps, although not close) between the observations and values computed with Veronese's equations is shown in Table 3. The usual equations based on Froude's law do not give as close an agreement. The prototype priming time was measured only on the Carron siphon.

HERBERT D. VOGEL,[26] ASSOC. M. AM. SOC. C. E. (by letter).—In 1929 there was not a single hydraulic structures laboratory in the United States, in a strict sense, although plans were being considered for eight to be established at various places.[27]

A recent *Bulletin*[28] of the National Bureau of Standards contains descriptions of fifty-three American laboratories, twenty-two of which are shown to be operated largely for the solution of open-channel problems. This phenomenal development may be due partly to the great increase in public work activities during the past few years, but inference is strong that some credence should be given the explanation that model studies return ample dividends. It should follow as a corollary, then, that small-scale models may be depended upon for the procurement of trustworthy information.

In an effort to find proof—or disproof—of the reliability of open-channel experimentation, this paper was tossed out as a challenge. The results, while disappointing, were nevertheless illuminating in their paucity, and the question could now be asked, "Are current studies being undertaken: (1) Because of the proved validity of the method; (2) because models are a cheap means of approximation; or (3) simply because it is fashionable to carry on 'scientific' research?" To run down the answer to this query circular letters were sent out from the U. S. Waterways Experiment Station during August, 1934, to more than fifty laboratories or individuals engaged in hydraulic research.

[26] Capt. Corps of Engrs., U. S. A., 3d Engrs., Schofield Barracks, Honolulu, Hawaii.

[27] "Hydraulic Laboratory Practice". Edited by the late John R. Freeman, Past-President and Hon. M. Am. Soc. C. E., p. 731, Am. Soc. Mech. Engrs., N. Y., 1929.

[28] "Hydraulic Laboratories of the United States", *Hydraulic Laboratory Bulletin, Series B*, National Bureau of Standards, First Revision, October 1, 1935.

It was requested in each case that information be furnished regarding the performance of any model tests, the results of which had been substantiated subsequently by results obtained in the field. Twenty of these letters were directed to addresses within the United States and the remainder were sent to foreign countries.

Replies were received from twenty-eight of those addressed, twelve of these being from laboratories within the United States. With a few notable exceptions, the replies contributed scarcely any information directly pertinent to the subject. From Germany came the citation of one instance of a model (scale, 1:45) of a dam that had produced results which, when compared with recorded data of the completed structure, were found to be accurate within 10 per cent. One correspondent in Italy reported that tests on siphons had failed to confirm the laws of similitude, whereas another stated that models of siphon spillways had been tested and found to reveal true information as to what could be expected in Nature.

A comparative wealth of data was received from Holland, outstanding among which were the following:

(*a*) Model studies to determine the efficiencies of two centrifugal pumps gave values varying from 0.75 to 0.87. In the prototype the efficiencies were found to be 0.80 in each case.

(*b*) After improving the Harbor of Breskens the intensity of wave action was reduced somewhat, as had been indicated by a model study.

(*c*) The results of six experiments with models (scale, 1:20) to determine the movement of stone on fascine mattresses were found to be in close agreement with the results obtained later in the Maas River.

(*d*) A 1:50 model of a discharging sluice gave depths of scour that were almost exactly verified in the field.

(*e*) A model (scale, 1:25) was operated to determine the discharge capacity of a sluice. Exact comparison with the data derived from full-scale performance has not been possible, but there appears to be a close agreement.

(*f*) A 1:5 scale model was built to study the flow of viscous fluids in suction pipes. Prototype and model flows were found to be exactly similar.

(*g*) Six models of navigation locks were experimented with in an effort to determine times of filling and forces acting upon the ships during lockage. When these locks had been built to full scale it was found that for two of them the times of filling were within 10% of those figures indicated by the model tests. Exact comparisons were not possible in the other cases, but it appeared that the general results were as had been predicted. Some indications of the produced forces were obtained from the full-scale structures, from which it appeared that differences of 15 to 25% were about the least that could be expected.

Sweden supplied information of two model tests which were subsequently verified by performances in full scale. One of these was to determine the degree of erosion that might be expected below the sector gates of a power plant; the other pertained to the procurement of data on a regulating weir.

Verification was received from England on the performance of tidal models; and data of surge tank experiments were also presented, together with those obtained later in the field. The results indicated an almost exact agreement between surge heights in model and in Nature, and revealed close agreement in periods.

Three of the twelve American laboratories that replied gave verifications of data obtained from model spillways, locks, and dams. Little or no information was received in justification of movable-bed models.

There can be no doubt that field verifications of small-scale experiments are difficult to obtain, but if models are to continue in their present high place as auxiliary aids for the hydraulic engineer, it will be necessary for their sponsors to procure positive proof of their reliability. Furthermore, it is just as important that the failures be revealed and recorded because, unless this is done, undue reliance may be placed on the results of certain studies from time to time. The scientist and the engineer must face facts as they are, prepared to modify their convictions as the need for so doing is evidenced. The several discussions of the paper carry this thought as an underlying consideration. The time for proselyting is past; careful scrutiny and study are now in order as means of determining what types of models can be relied on for quantitative data; what kinds will give reasonably accurate qualitative effects; and which are capable of nothing but deceit.

An extremely common sense viewpoint of the entire question has been presented[29] editorially. One paragraph appearing particularly worthy of quotation is as follows:

> "The publication of results, with particular reference to any new form of technique evolved, is greatly to be encouraged, in all hydraulic model work, no less, of course, than in any other branch of applied mechanics; for the guidance so provided may serve not only to help others to avoid the many pitfalls, but may effectively reduce the cost and labour involved. Certainly the cost of such investigations cannot be lightly undertaken, the labour entailed both in the laboratory and often also in the very important work of collecting essential data for the experimental work from the field, is considerable. Speaking generally, however, in cases where the need for model investigations is felt, the cost will be small in comparison with the scheme in hand."

This comment was written with the writer's paper in mind.

THE HYDRAULIC JUMP IN TERMS OF DYNAMIC SIMILARITY

BY BORIS A. BAKHMETEFF,[1] M. AM. SOC. C. E., AND
ARTHUR E. MATZKE,[2] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. HUNTER ROUSE, SHERMAN M. WOODWARD, ROBERT E. KENNEDY, L. STANDISH HALL, MORROUGH P. O'BRIEN, F. V. A. E. ENGEL, BALDWIN M. WOODS, J. C. STEVENS, NOLAN PAGE, ANDREI I. IVANCHENKO, F. T. MAVIS AND ANDREAS LUKSCH, I. M. NELIDOV, AND BORIS A. BAKHMETEFF AND ARTHUR E. MATZKE.

SYNOPSIS

Since Bidone's classical "Memoire"[3], the first to describe the hydraulic jump, this fascinating and puzzling phenomenon has been the subject of repeated experimental investigation. Most of the work has dealt with what may be termed the "vertical" elements of the jump, such as the relation between the lower and upper stages, the height of the standing wave, etc. Scarcely any data are available, at least in systematic form, with regard to what may be termed the "longitudinal elements", such as the length of the jump, the profile of the surface of the roller, etc. The importance of such data is obvious. In designing stilling-basins at the toes of spillways, in laying out devices to prevent erosion below sluices, and in other similar cases, knowledge of the longitudinal elements is indispensable.

During 1932–33 the longitudinal elements of the jump was the subject of systematic research in the Fluid Mechanics Laboratory of Columbia University, in New York, N. Y. A particular feature of the work was, that in interpreting and systematizing the results obtained, recourse was taken to the principle of dynamic similarity and the final data were presented in generalized dimensionless form. Dimensionless presentation in terms of

dynamic similarity is known to have yielded splendid results and has become a matter of course when dealing with flow in closed conduits. On the other hand, its application to open flow, with the exception of models of rivers, has not been as widespread as could be expected. It also appears that the basic premises which should govern the approach to open-flow problems, are not always clearly understood and that at times investigators are prone to select parameters non-judiciously. An example is the frequent use of the so-called "Boussinesq number."

The experiments described herein were referred to a general dynamic characteristic, "the kinetic flow factor"[4]. The results obtained seem to have confirmed the usefulness of the general methods applied and are claimed to have given the first comprehensive picture of the longitudinal features of the hydraulic jump in general.

THEORETICAL PREMISES

To facilitate a comprehensive approach, a brief recapitulation will be first given of the theoretical premises, which underlie the subsequent treatment.

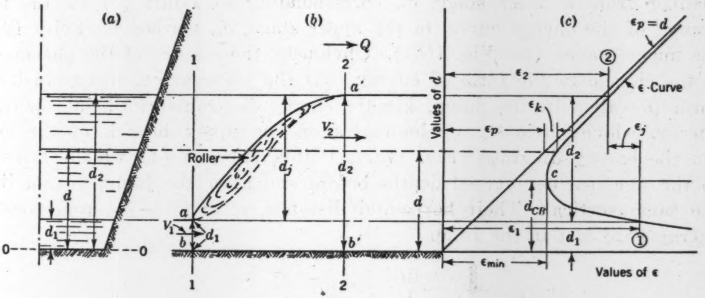

FIG. 1

Specific Energy Curve.—In treating problems of varied flow in open channels, it has become customary to refer the motion to a "specific energy curve"[5] represented in Fig. 1(*c*). The constant discharge in a canal of given cross-sectional area, *A*, with a varying depth, *d*, is expressed by *Q*. For each depth one may estimate the energy head (the energy in a unit weight of liquid), referred to a datum line, 0-0, drawn through the bottom of the canal. The potential energy head is $\epsilon_p = d$; the kinetic energy head is,

$$\epsilon_k = \frac{V^2}{2g} = \frac{Q^2}{2\,g\,A^2_d} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

---

[4] "Hydraulics of Open Channels", by Boris A. Bakhmeteff, M. Am. Soc. C. E., Engineering Society Monographs, McGraw-Hill Co., 1932, p. 64.

[5] *Loc. cit.*, p. 32.

in which, A_d is the cross-sectional area at the depth, d. Their sum is equal to:

$$\epsilon = \epsilon_p + \epsilon_k = d + \frac{V^2}{2g} = d + \frac{Q^2}{2\,g\,A^2_d} \quad \ldots\ldots\ldots\ldots\ldots (2)$$

which is the total specific energy of flow, being a function of the depth, d, only. The graph of the ϵ-curve (Fig. 1(c)) indicates, that the energy contents vary with the depth, increasing indefinitely for very large and very small values of d. For each discharge there is a definite point, c, which marks the lowest possible energy, ϵ_{min}, compatible with the given discharge and the given canal cross-section. The flow at the point, c, is said to be "critical", the corresponding depth, d_C, being the "critical depth".

For the important case of a rectangular channel, with a width, B, and with $q = \frac{Q}{B}$, the discharge per unit width, the specific energy is:

$$\epsilon = d + \frac{q^2}{2\,g\,d^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

and the critical depth at which the energy content is minimum is expressed by,

$$d_C = \sqrt[3]{\frac{q^2}{g}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

The Hydraulic Jump.—Referred to the specific energy curve, the hydraulic jump is a local phenomenon by means of which flow passes in a rather abrupt manner from a lower stage, d_1, corresponding to Point (1) on the lower branch of the energy curve, to the upper stage, d_2, marked by Point (2) on the upper branch (see Fig. 1(b)). Obviously, the essence of the phenomenon is the change in the form of energy. At the lower stage, energy in kinetic form prevails; in the jump, kinetic energy is transformed into potential energy, which obviously predominates on the upper branch of the curve. On the energy diagram (Fig. 1(c)), Points (2) and (1) which correspond to the so-called conjugated depths before and after the jump, do not lie on the same vertical. Their horizontal distance, $\epsilon_j = \epsilon_1 - \epsilon_2$, represents the energy head lost in the jump.

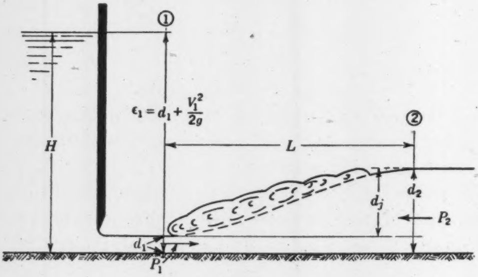

FIG. 2

Similar to many other cases of fluid dynamics in which one deals with abrupt variations in the forms of flow, a comprehensive solution is reached by applying (as first suggested by Bélanger) the "momentum principle".

It is customary to make certain fundamental assumptions when applying the momentum principle. These assumptions underlie the familiar equations relating to the hydraulic jump and should be kept clearly in mind.

In Fig. 1(*b*), or in Fig. 2, Sections (1) and (2) refer to the "beginning" and to the "end" of the jump. Thus, they delimit the jump, schematically, separating it from the adjoining reaches of gradually varied flow. Motion at Section (1), preceding the toe of the roller, is free and still is not influenced by the roller. The stream lines are parallel. Therefore, the pressure distribution is assumed to follow the hydrostatic law. This means that the potential energy referred to 0-0 (Fig. 1), throughout the stream is the same and is equal to the depth, d, which permits expressing the average energy by the simple expression, Equation (2). Section (2) represents the "end" of the jump. It is supposed to be selected so that the expansion of the live jet under the roller has ceased. In other words, the curvature of the stream lines, which features the flow in the jump proper, is no longer present and the stream filaments have again become parallel, with the hydrostatic distribution of pressure again restored. For this reason the energy may again be computed by the simple expression, Equation (2).

The assumption of parallel filaments of flow in Sections (1) and (2) which leads to hydrostatic distribution of pressure, permits one to estimate the pressure components across these sections, which effectuate the change of momentum in the liquid body as the respective resultants of the hydrostatic pressure,

$$P = \gamma \, A_d \, z_0 \quad \ldots\ldots (5)$$

in which, γ is the specific weight of the fluid, and z_0, the depth of the center of gravity of the respective section below the free surface.

For a jump in a horizontal flume, the only other force component acting in the direction of the flow (and thus contributing to the change of momentum) is the resultant of "external" friction forces, acting between the liquid body, $a\ a'\ b'\ b$ (Fig. 1(*b*)), and the solid boundaries (the bottom and the walls) of the canal. Compared to the action of the highly disturbed and turbulent motion, engendered inside the liquid body in the roller and in the expanding vein, and which naturally results in pronounced losses of energy head, the shearing stresses acting in the boundary layer between the jump and the walls are taken to be insignificant in their ultimate effect. It is customary, therefore, simply to neglect these outward forces and to eliminate them from "the picture" when establishing the equation embodying the momentum principle. In other words, the familiar equations, giving the ratios between the stages before and after the jump, are obtained by neglecting the friction forces, acting on the comparatively short and insignificant reach, L (Fig. 2), over which the jump extends.

For a rectangular channel, considering a unit width with a discharge, q, the difference of the hydrostatic pressure is:

$$P_1 - P_2 = \gamma \left(\frac{d^2_1}{2} - \frac{d^2_2}{2} \right) \quad \ldots\ldots (6)$$

The change of momentum per second, with the mass flow, $\frac{q\,\gamma}{g}$, is $\frac{q\,\gamma}{g}\,(V_2 - V_1)$. Equating and transforming, one obtains:

$$\frac{2\,q^2}{g} = d_1\,d_2\,(d_1 + d_2) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

from which are developed the well-known equations, giving the relations between the conjugated depths:

$$d_2 = \frac{d_1}{2}\left[-1 + \sqrt{1 + \frac{8\,q^2}{g\,d^3_1}}\,\right] \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

and,

$$d_1 = \frac{d_2}{2}\left[-1 + \sqrt{1 + \frac{8\,q^2}{g\,d^3_2}}\,\right] \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

Another form is obtained by substituting d_C from Equation (4), thus:

$$d_2 = \frac{d_1}{2}\left[-1 + \sqrt{1 + \frac{8\,d^3_C}{d^3_1}}\,\right] \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

and,

$$d_1 = \frac{d_2}{2}\left[-1 + \sqrt{1 + \frac{8\,d^3_C}{d^3_2}}\,\right] \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

Dynamic Similarity.—The Kinetic Flow Factor.—In Equations (10) and (11) the relation between the stages is made to depend on the ratio of the critical depth to the respective depths, d_2 and d_1. With reference to Fig. 1(*c*), the ratio, $\frac{d_C}{d}$, marks the position of the flow on the energy curve. The larger the ratio, $\frac{d_C}{d}$, the greater will be the velocity of flow and, consequently, the relative part of the kinetic energy component in the total energy head. In fact, each point on the energy curve characterizes a "state of flow", which may be numerically qualified by what has been termed,[4] the "kinetic flow factor"; thus:

$$\lambda = 2\,\frac{\epsilon_k}{\epsilon_p} = \frac{V^2}{g\,d} = \frac{q^2}{g\,d^3} \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

which gives a measure of the "kineticity of flow", expressed by twice the ratio of the kinetic energy head to the potential energy head contained in each pound of liquid, flowing at the depth, d. The reason for the coefficient, 2, in Equation (12) is that, in the critical state (that is, when the flow is at the critical depth, d_C), the value of λ becomes:

$$\lambda_C = \frac{\frac{q^2}{g}}{d^3_C} = \frac{\frac{q^2}{g}}{\frac{q^2}{g}} = 1 \ldots\ldots\ldots\ldots\ldots\ldots (13)$$

In other words, the kinetic flow factor at the critical depth is $\lambda = 1$. Flow on the upper branch of the ϵ-curve, with $d > d_C$, is governed by the condition, $\lambda < 1$; flow on the lower branch, with $d < d_C$, is governed by the condition, $\lambda > 1$. Obviously, the factor, λ, is a general dimensionless characteristic of the dynamic conditions of flow. In fact, in the terms ordinarily used in studies of dynamic similarity the kinetic flow factor, λ, is equivalent to the so-called Froude number.

It is important, in this instance, to make as clear as possible the premises that underlie the treatment of open-flow problems in terms of dynamic similarity. Two basic cases must be distinguished: First, that in which the most important agencies are resistances of the frictional type, analogous to those occurring in a pipe; and, second, that in which the features of the phenomenon are, for the most part, determined by the action of gravity. The phenomena in the first case were first studied comprehensively by Osborne Reynolds.[9] Flow in these circumstances will be dynamically similar, when the same ratio persists between the inertia effects (mass times acceleration, in the Newtonian equation of motion) and the frictional resistances, the source of the origin of which is the general property of matter known as viscosity. In this case the factor expressing, numerically, the ratio of the inertia forces to the viscous forces, has the form of the so-called Reynolds number:

$$\mathsf{R} = \frac{V l}{\nu} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

in which, $\nu = \frac{\mu}{\rho}$, the kinematic viscosity, and l, an appropriate longitudinal parameter, such as the diameter or the radius of a closed conduit. A number similar in structure to Equation (14) would be in order, for example, when studying the frictional resistances in uniform canal flow. In that case, l could be the depth, or any other characteristic geometric dimension, provided the cross-sections compared were geometrically similar.

In the second case, the phenomena are principally determined by action of gravity. This was the problem faced by Froude, when seeking to compare the resistances offered by surface waves created by the motion of a vessel. Dynamic similarity, in this case, representing a constant ratio between inertia forces and gravity action, is expressed by a factor known as the Froude number, and usually given in the form:

$$\mathsf{F} = \frac{V}{\sqrt{g\,l}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

in which, l is an appropriate longitudinal factor, such as the length of the ship.

In analyzing open-flow cases it must be first remembered, that the principle in general may be applied to geometrically similar cases only. Many mistakes are known to have arisen from a failure to observe this fundamental rule.

Furthermore, one must determine which of the two types of forces, gravity or friction, are preponderant in each specific case and which of the two, therefore, should be accepted as the principal agent, affecting the flow. As is well known, one cannot "cater" to both types of forces simultaneously and, therefore, a definite choice must be made.

---

[9] *Philosophical Transactions*, Royal Soc., 1883.

Finally, it must be borne in mind, that the longitudinal parameter, l, in Equation (14) or Equation (15), cannot be selected at random. In fact, the parameter must correspond to the essential features of the particular case; it must be connected inherently with the physical agencies that influence one or the other of the two cases. For example, in the case of the hydraulic jump, the friction forces are neglected deliberately. The phenomenon of the "jump" is considered to depend entirely on the action of gravity, which expresses itself in the hydrostatic pressures and causes the change of momentum.

Thus, a dynamic characteristic of the Froude type is in order. A longitudinal parameter, germane to the physical essence of the phenomenon, which embodies transformation of the form of energy, is the depth, d, representing the potential energy of the flow. Hence, the Froude number, $\mathsf{F} = \frac{V}{\sqrt{g\,d}}$, which is equivalent to the kinetic flow factor, $\lambda = \frac{V^2}{g\,d}$.

If $\lambda = \frac{V^2}{g\,d}$ is an appropriate dynamic characteristic of the Froude type, it would naturally follow that flow in the two cases, possessing similar values of λ, would assume similar forms. Thus, for example, the ratio of the conjugated depths, $\frac{d_2}{d_1}$, or, respectively, $\frac{d_1}{d_2}$, in a hydraulic jump (see Equations (10) and (11)) may be expressed in terms of the kinetic flow factor, by substituting Equation (12) in Equations (8) and (9) which gives,

$$\frac{d_2}{d_1} = \frac{1}{2}\left[-1 + \sqrt{1 + 8\,\lambda_1}\right] \qquad (16)$$

and,

$$\frac{d_1}{d_2} = \frac{1}{2}\left[-1 + \sqrt{1 + 8\,\lambda_2}\right] \qquad (17)$$

in which, λ_1 and λ_2 are the respective kinetic flow factors in the sections before and after the jump.

Referring to the so-called Boussinesq number which, as indicated previously, is being used improperly to an ever-increasing extent:

$$\mathsf{B} = \frac{V}{\sqrt{g\,r'}} \qquad (18)$$

is an expression of the "Froude type" (Equation (15)), in which, $r' = \frac{2\,A}{\text{wetted perimeter}}$, is twice the value of Chezy's hydraulic radius. The hydraulic radius is related inherently with friction effect. It would be quite appropriate as a factor in a characteristic of the Reynolds type (Equation (14)) as, for example, in a study of friction forces in uniform flow; but it is entirely out of place in a case (such as the "jump", or flow through a structure) in which the motion is primarily dependent on gravity action. Gravity has no relation whatever to the hydraulic radius, the latter being thus a parameter that bears no physical relation to the essence of the case.

Dimensionless Representation.—Equations (16) and (17) are given in terms of ratios; that is, in a dimensionless form, which is becoming common practice in engineering science. Dimensionless representation results in equations of the most general type. Equations (16) and (17), for example, do not refer to any particular jump. They apply equally to a jump at the foot of the Boulder Dam and a small-scale model in a laboratory flume. The ratio of the depths will be the same when, and if, the kinetic flow factor is identical.

Assume, for example, that the depth of flow in any structure is d_p, with a unit-width discharge, q_p. Assume, furthermore, that the model is to be reproduced on a geometrical scale of 1:10 so that the depth of flow is $d_m = \frac{d_p}{10}$. The discharge in the model, reproducing dynamically similar conditions, requires identity of the Froude number, or an identical value of λ. Thus,

$$\frac{q^2{}_m}{d^3{}_m} = \frac{q^2{}_p}{d^3{}_p} \quad \text{.............................(19)}$$

or, with a scale of 1:10:

$$q_m = q_p \sqrt{\frac{1}{1\,000}} = 0.0316\, q_p$$

General Dimensionless Characteristics of the Jump in Terms of λ.—The different features of the jump may be expressed in a useful form as ratios, $d'_1 = \frac{d_1}{\epsilon_1}$; $d'_2 = \frac{d_2}{\epsilon_1}$; etc. The physical meaning is made clear by referring to Fig. 2, in which, ϵ_1 is equal to the head, H, provided the outflow losses are omitted.

Referring to Fig. 2: $d'_1 = \frac{d_1}{\epsilon_1}$; $d'_2 = \frac{d_2}{\epsilon_1}$; $d'_j = d'_2 - d'_1$; $V^2{}_1 = 2g\,(\epsilon_1 - d_1)$; and, therefore,

$$\frac{(V'_1)^2}{2g} = 1 - d'_1 \quad \text{........................(20)}$$

Furthermore, $\lambda_1 = \frac{2\,(1 - d'_1)}{d'_1}$; and,

$$d'_1 = \frac{2}{2 + \lambda_1} \quad \text{.........................(21)}$$

By means of Equation (21) and bearing in mind that $(u'_2) = u'_1 \left(\frac{d'_1}{d'_2}\right)$ one can also determine the energy in Section (2) after the jump,

$$\epsilon'_2 = d'_2 + \frac{(V'_2)^2}{2g} \quad \text{.....................(22)}$$

and the loss in the jump is,

$$\epsilon_j' = 1 - \epsilon_2' \qquad\qquad (23)$$

The different elements of the jump may be traced[7] in terms of d'_1, or they may be presented directly in terms of the kinetic flow factor resulting in the curves of Fig. 3.

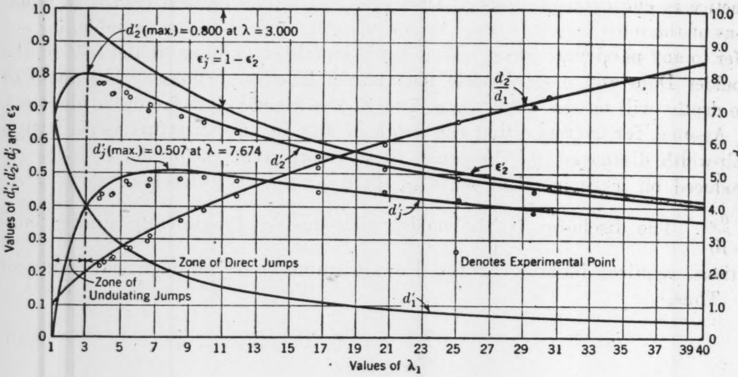

FIG. 3

These curves represent the most general dimensionless characteristics of the jump in terms of dynamic similarity. The following special features of the curves as drawn are to be emphasized as they bear directly on the experiments to follow: (1) The highest possible theoretical stage, $d'_2 = 0.800$, is reached at $\lambda_1 = 3$, the corresponding value of the initial depth being $d'_1 = 0.4$; and, (2) the d'_j-curve shows that the jump attains its maximum height at $\lambda_1 = 7.674$, with $d'_j = 0.507$.

It should be emphasized that the characteristics as given in Fig. 3 result from theoretical relations obtained by using the momentum principle. They apply to a jump in a horizontal flume, the slight effect of friction forces on the outward boundaries being neglected. It remains for experiments to show, in general, whether the foregoing premises, which permit a simple theoretical approach, are justified. The curves in Fig. 3 are supported by results obtained from experiments described subsequently. On the whole, theory and observation agree most satisfactorily. As one should expect the actual observed values of d_2 and d_j are somewhat lower than the theoretical values. This is due to the neglected effect of external friction. In general, experiments in flumes of larger size and on a larger scale, in all probability, would make the deviations still smaller.

EXPERIMENTAL PROCEDURE

The Flume.—The experiments supporting this paper were run in the varied-flow flume of the Fluid Mechanics Laboratory, at Columbia University. The tilting device, a general outline of which is given in Fig. 4, was 20 ft long, 6 in. wide, and 22 in. high; it was made of welded metal. Water was fed to the supply basin, by a 5-in. vertical pump, the basin being provided with suitable baffles and a regulated overflow.

---

[7] "Hydraulics of Open Channels", Eng. Societies Monograph, 1932, p. 248.

Due to limited space and to peculiarities of the foundations the sump was of rather restricted volume, built into the lower part of the supply basin with a return channel substantially at the same level, placed under the flume. The discharge was measured by a special device designed on the principle of the "critical depth meter". The device was calibrated by volumetric measurement and was also compared with a sharp-crested weir, using the Rehbock and the Swiss Engineering Society's coefficients. The two methods gave practically identical results. It is assumed that the discharge is known accurately to within 1 per cent.

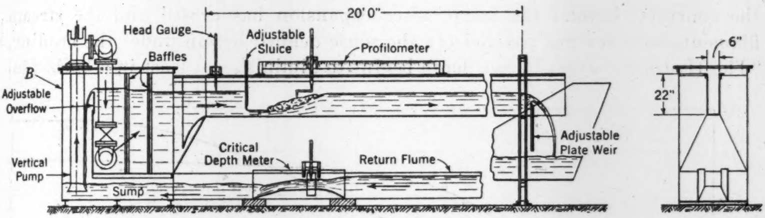

FIG. 4

In the particular experiments referred to in this paper, the bottom of the flume was kept horizontal, and the "rapid" flow necessary for the formation of a jump, was produced by an adjustable sluice. The tail-water was regulated, and thus the location of the jump was controlled by means of an adjustable plate weir at the end of the flume. A profilometer permitted readings that were accurate to within 0.001 ft. A view of the jump "in action" has been presented elsewhere[8].

A few words of explanation may be useful to clarify some of the problems connected with measuring the hydraulic jump. The jump appears to the eye as an erratic phenomenon subject to violent and apparently inordinate oscillations. Thus, the position of the toe of the jump varies continuously, up stream and down stream. Even greater agitation is noticeable in the roller to which, at first, one may be led to doubt whether any uniform or stable laws apply. However, it is known that irrespective of the apparent convulsions, the basic dynamic relations applying to the jump (such as the ratio between the depth, d_1 and d_2) are unexpectedly uniform and constant when taken as average values over a given period. Moreover, no matter how violently the position of the jump appears to vary, a stable and definite average reading of a vertical element may be obtained over a period when, for example, the position of the pointer is adjusted so that the flow oscillates to one side and then the other, around the selected position, at more or less equal time intervals. It is in this sense that an average profile of the roller covering the expanding "live vein" of the jump may be obtained by successive vertical readings at chosen points.

---

[8] *Civil Engineering*, November, 1934, p. 564.

Further explanation is necessary with regard to the term, "length of the jump". The beginning of the jump, at the toe of the roller, is well defined; but there has been some confusion as to what constitutes the "end of the jump". Some writers[9] assume the end to be substantially at a point where adverse flow is no longer observable. In the writers' experience, this definition would determine the end of the roller, and not the end of the jump.

The roller is usually shorter than the jump as a whole. Furthermore (and this concept is essential), the roller is an accompanying feature only. The essential function of the jump is to transform the energy from kinetic to potential. This is accomplished in the expanding vein under the roller. The jump is thus characterized pre-eminently by an increasing depth of flow. On the contrary, beyond the jump, after expansion has ceased and the stream filaments have become parallel (in the sense defined herein under the heading, "The Hydraulic Jump"), the depth begins to diminish—at least in a horizontal flume. In other words, in this region, flow is characterized by the lowering of the surface level. It is logical under such circumstances to conceive of the end of the jump as a section at which the surface level reaches its maximum height and at which the rising curve of the expanding vein under the roller passes into the "drop" surface of the subsequent reach of gradually varied flow. In other words, as shown schematically in Fig. 2, the end of the jump is at Section (2) where the depth, d_2, has reached its maximum value. In practical experimental work the difficulty lies in the fact that the entire surface curve in this region is very flat and subject to continuous oscillations. In most cases, therefore, it is rather impossible to determine the position of the end section by direct observation. The method used was to trace profiles based on average observations, and then to select the end point from the drawing thus obtained. It was necessary to trace such profiles for each run (see Fig. 5). Even then, due to the flatness of the curves, all one can do

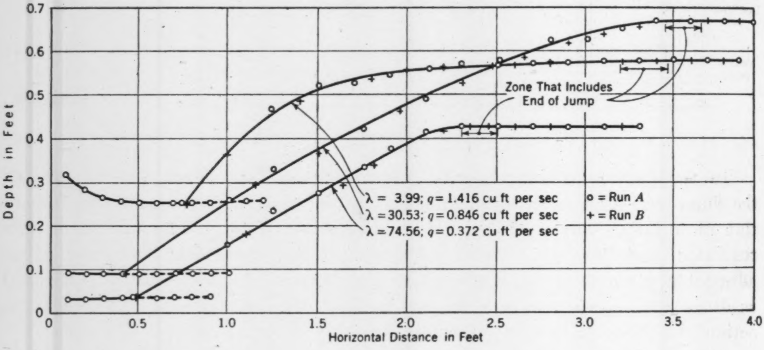

FIG. 5

---

[9] See, for example, *Civil Engineering*, May, 1934.

is to establish a zone within which the position of the end section is more or less arbitrary. Obviously, in this instance, as in so many other cases of experimental engineering, one is dealing with a "transition zone".

Another delicate operation is the measurement of the initial depth at the lower stage in Section (1), (Fig. 2). The higher the kineticity, the smaller will be the value of d_1. In Equation (12), the depth, d_1, appears as a third power. Any experimental error, therefore, affects the final result seriously. These facts define a natural limit to experimentation. One cannot increase λ_1 by decreasing d_1 beyond a reasonable amount. Then (see Fig. 2), the initial depth must be measured at the toe of the roll, which is in an oscillating state and which obviously interferes with the pointer of the profilometer. The procedure used was again to trace an auxiliary profile of the free vein over a certain stretch by moving the jump somewhat downward. After the profile was thus determined, the jump was brought back into position, and the respective depth, d_1, was taken from the auxiliary tracing. The procedure is clearly demonstrated in Fig. 5.

The actual experiments were run during a period of about ten months, beginning December, 1932. At least one-half the time was spent on calibration and preliminary work, in which methods of procedure were gradually developed. Most of these preliminary results were discarded and, with the experience and skill gained, a second and final set was run. For each run a certain discharge, q, and a certain depth, d_1, were maintained over the entire period of the experiment. Then, a double series of profile observations were made, one going down stream and then returning up stream. The discharge was measured at the beginning and at the end of each run. Only such runs were considered satisfactory for further use and interpretation, which showed permanent discharge and which, in addition, registered coinciding profile readings. On the whole, experimenting with the jump is tedious work, demanding patience and perseverance. At best, in a day of 8 or 9 hr, only two successful runs were possible.

Results and Conclusions

The principal results of the experiments are summarized in Table 1. The observed values are q, d_1, d_2, and the length of the jump, L. For the latter (Table 1, Columns (4) and (5)) the experimental data are given in the form of a range as shown by Fig. 5. The other tabular values were computed. The basic factor is, $\lambda_1 = \frac{q^2}{g\,d^3_1}$; and the initial energy, $\epsilon_1 = d_1 + \frac{q^2}{2g\,d^2_1}$. The ratio, $\frac{d_2}{d_1}$, in Column (12), Table 1, is the quotient, and d_j in Column (7) is the difference of the values in Columns (3) and (2). The dimensionless factors in Columns (9), (10), and (11), Table 1, are obtained by dividing Columns (2), (3), and (7) by Column (8).

Length of the Jump.—The first and immediate aim of the research undertaken was to obtain comprehensive data concerning the length of the jump. Columns (13) to (20), Table 1, give the length in terms of dimensionless

ratios, the observed *L*-values, Columns (4) and (5), being divided by Columns (2), (3), (7), and (8). The results are represented in Fig. 6. In tracing the curves, it is obvious that they must pass within the plotted regions, indicating the possible range of the *L*-values. Then, the investigator should be guided by the interrelation between d_2, d_1, d_j, etc., as illustrated by Fig. 3. In other words, when a certain region happens to be marked by particularly scattered data, the curve in question can be traced, nevertheless, by making use of some other curve, which in that particular region will be experimentally defined with better precision. The upper limit of λ_1 practicable in the case, could not be extended beyond 70 to 80 (see Fig. 6). The lower limit (slightly more than 3.5) is determined, on the other hand, by certain physical features inherent in the phenomenon. As indicated previously in another connection,[10] the maximum d_2-point in Fig. 3, corresponding theoretically to $\lambda_1 = 3$, delimits two possible forms of the jump: (1) The direct jump illustrated by Fig. 5, and the undulating jump in Fig. 7. Obviously, the region near $\lambda_1 = 3$ is a zone of transition, since it is reasonable to anticipate that the change to the undulating form is gradual and that the undulations increase as λ_1 is diminished. Fig. 7 gives a striking confirmation of the foregoing statements. The discharge being kept constant, the sluice was gradually opened and the kineticity decreased. The undulations become more and more pronounced. No numerical values for λ are given in the diagram, because the vein at the lower stage ceased to be parallel. Due to curvature the distribution of pressure is no longer hydrostatic and the simple expression (Equation (2)) for ε is no longer applicable. One may gather from Fig. 3 that the effect of boundary friction (disregarded in the Bélanger theory) would be to shift the actual point, d'_2 (maximum), somewhat to the right. For this reason, the zone dividing direct and undulating jumps would be actually at a somewhat greater value than the theoretical, $\lambda = 3$; possibly $\lambda = 3.5$, or 4.0.

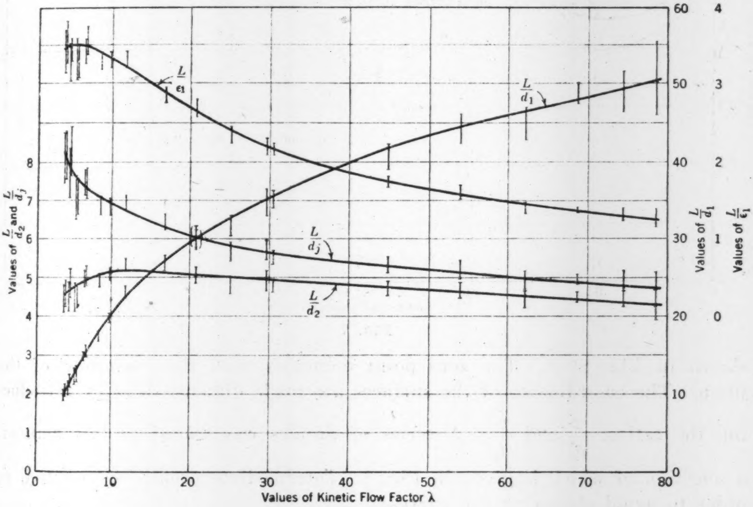

FIG. 6

Generalized Profiles of the Jump.—In plotting the profiles, in Fig. 5, the writers became impressed by the fact that the outlines of apparently such an irregular and capricious phenomenon as the jump finally proved to be unexpectedly regular. The idea naturally arose to reduce all the observed profiles to some unified dimensionless form. After certain trials, it appeared expedient to use the height of the jump, $d_j = d_2 - d_1$, as the parameter for reference. The different profiles were referred to a system of co-ordinates, shown in Fig. 8(a). The zero point coincides with the beginning of the jump. The co-ordinates of the surfaces are made dimensionless by introducing the ratios, $\frac{x}{d_j}$ and $\frac{y}{d_j}$. A series of profiles was traced in this manner, a selection of which is given in Fig. 8. Intermediate profiles are omitted in order to avoid obscuring the curves.

---

[10] "Hydraulics of Open Channels", Eng. Societies Monograph, 1932, p. 249

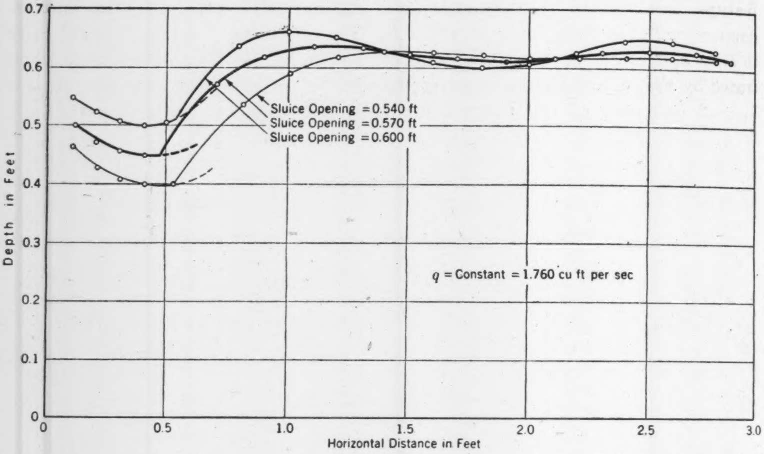

FIG. 7

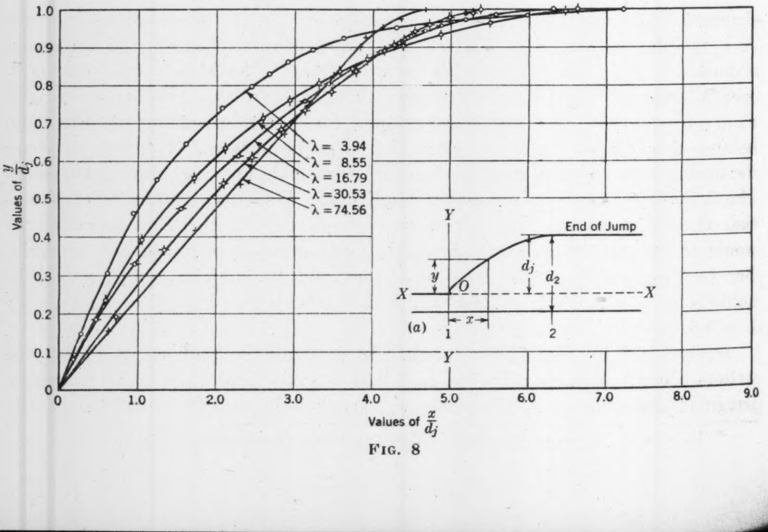

FIG. 8

The jumps embodied in these profiles are typical of a large variety. The initial depth varies from 0.03 to 0.25 ft; the length, L, from 1.5 to more than 5 ft; and the ratio, $\frac{d_2}{d_1}$, changes from about 2 to nearly 12. Notwithstanding this variety, the profiles, when presented in terms of dimensionless coordinates, range within a rather restricted area. A further step is reached by using the tri-dimensional presentation given in Fig. 9.

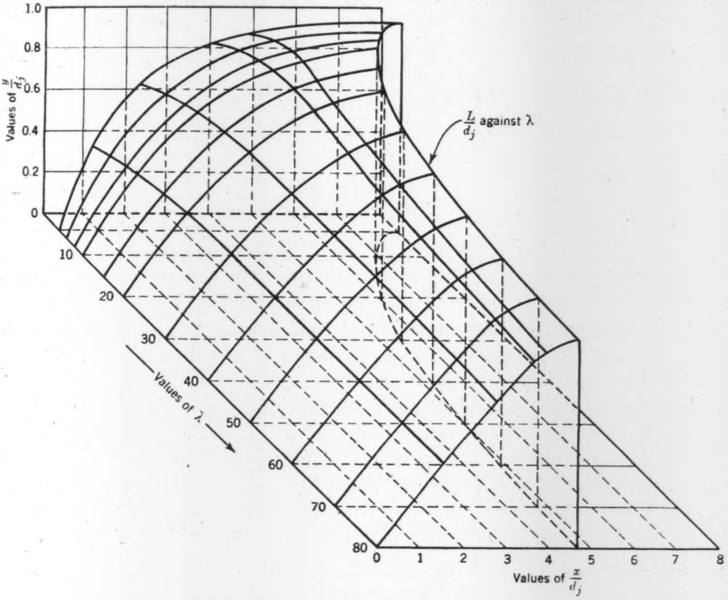

FIG. 9

Conclusions.—The results obtained by the writers may be summarized by stating that, by plotting dimensionless ratios against the kinetic flow factor, a consistent unified set of curves has been obtained. The most consistent regularity is that of the $\frac{L}{d_2}$-curve, which is in accord with certain practical indications scattered throughout recent periodical literature. The form of the $\frac{L}{d_2}$-curve, which shows a maximum point, should be considered in connection with the outline of the curves in Fig. 3.

The curves are offered to the Engineering Profession as seemingly the broadest summarized experimental evidence available at the moment. It is felt, that they may be useful in connection with practical engineering design.

The writers are fully conscious of the fact that the size of the flume and certain imperfections of its construction militate against a greater precision in the results. It is believed, however, that the general aspects of the phenomenon of the hydraulic jump have been made clearer.

ACKNOWLEDGMENT

The experiments described in this paper were conducted in the Fluid Mechanics Laboratory, Department of Civil Engineering, Columbia University. Special acknowledgments are due Dr. Hunter Rouse for the preparation of Fig. 9 and for other valuable assistance.

APPENDIX

NOTATION

The following notation, introduced in this paper, is consistent with the American Tentative Standard Symbols for Hydraulics[11]:

d = depth of flow = potential energy head, ϵ_p; d_p = depth of flow in the prototype; d_m = depth of flow in a model.
g = acceleration due to gravity.
j = a subscript denoting "hydraulic jump".
k = a subscript denoting "kinetic"
l = an appropriate longitudinal parameter.
m = a subscript denoting "model"
p = intensity of pressure; as a subscript, p denotes "prototype".
q = discharge per unit width.
r = radius; $r' = \dfrac{2\,A}{\text{wetted perimeter}}$.
x = variable distances from the Y-axis
y = variable distances from the X-axis.
z = elevation head; z_0 = depth of the center of gravity of a section below the free surface.
A = area of section; A_d = area at depth, d.
B = Boussinesq number.
C = Chezy's coefficient; as a subscript, C, denotes "critical".
F = force; total force.
F = Froude's number.
H = total head at any point.
L = length of hydraulic jump
P = total pressure.
Q = rate of discharge.

---

[11] A. S. A.—Z10b—1929.

R = hydraulic radius.
R = Reynolds number.
V = average velocity at a section.
γ = specific weight of a fluid.
ϵ = energy head, or total specific energy of flow; ϵ_p = potential energy; ϵ_k = kinetic energy, ϵ_j = energy loss in the hydraulic jump.
λ = kinetic flow factor.
μ = absolute viscosity = $\nu\ \rho$.
ρ = density.
ν = kinematic viscosity $= \dfrac{\mu}{\rho}$.

DISCUSSION

Hunter Rouse,[12] Esq. (by letter).—In full accord with modern trends in the science of fluid mechanics, the authors have recognized in this familiar hydraulic phenomenon a physical problem which may be fully understood only through physically correct methods of approach. By means of dimensionless analysis of the phenomenon according to the Froude criterion of dynamic similarity, the hydraulic jump has finally been given definite form and character in terms of a universal parameter, with the determination of general relationships involving jumps of every size and nature.

Too much credit cannot be given for the devotion of many hours to tedious measurement, computation, and discussion, during which the writer was often a privileged witness. Only those who have experienced the high degree of turbulence and accompanying fluctuation in the region of the jump can appreciate the care such measurements entail; yet far from the expected scattering of points, the authors' results show remarkable co-ordination. Aside from presenting new data covering systematically a great range of conditions, and a correct physical interpretation of these data, the authors' paper serves the excellent purpose of clarifying a number of basic points often confused in previous investigations. The writer adds the following discussion in the hope that it may throw further light upon so important a type of fluid motion.

During the century following Bidone's first description of the jump, hydraulicians were slow to conclude that the popular energy principle had to be abandoned for the principle of momentum before the height of the jump could be computed successfully. Although the application of the momentum principle had been suggested shortly before the middle of the Nineteenth Century by Bélanger, emphasized later by Bresse, and finally discussed at length by Unwin in the Encyclopedia Britannica in 1880, as late as 1916 many publications, both in the United States and abroad, still held persistently to the assumption of constant energy according to the Bernoulli theorem.

Various writers, however, developed empirical equations for the relation of the two depths, believing that energy loss must exist; typical of these is that of Merriman, included in the early editions of his text on hydraulics.[13] Whatever the relationship used, abundant experimental results were quoted by the different writers, the best-known data being those of Bidone (1818), Darcy-Bazin (1856), Ferriday-Merriman (1894), Gibson (1913), and Riegel-Beebe, of the Miami Conservancy District (1917). With the perfection of the indoor hydraulic laboratory in Germany considerable study was given the jump, of which the experiments carried out under Koch at Darmstadt are good examples.[14] Rehbock made constant use of the basic momentum principle in the design of spillway aprons,[15] and the much-quoted thesis of Böss on open-channel flow[16] discussed the position of the jump with regard to channel slope and discharge. It is noteworthy, however, that little mention was made by any of these investigators of the longitudinal profile; nor had successful attempts been made to treat the problem as one of dynamic similarity.

[15] "Die Verhütung schädlicher Kolke bei Sturzbetten," von Th. Rehbock, *Der Bauingenieur,* 1928, Heft 4, 5.

Apparently, Groat and Kennison were the first to make use in this case of a term similar in form to the Froude number,[17] but it remained to Safranez,[18] in a series of experiments conducted in the laboratory of the Technische Hochschule, at Berlin, to undertake a two-dimensional physical study of the problem, in which constant use was made of the foregoing dimensionless term—without realization that it was actually the Froude number. Safranez gave an empirical relationship for the length of the jump, stating, in addition, that it was approximately 4.5 times the down-stream depth and that the slope of the jump was practically constant. (Refer to Figs. 8 and 9 of the authors' paper these two diagrams deserve careful study, as they show in comprehensive form the actual variation of the length and the shape of the jump with the Froude number, and the transition to the undular form as this number approaches a minimum.)

Following closely upon the publication of the foregoing papers, a controversy arose abroad over the part played by the surface roller in the apparent energy loss accompanying the jump. The roller was held by several (in particular by Kozeny[19]) to be of negligible influence, and various experimental and theoretical methods are still being used and misused to prove both sides of the case. Einwachter, whose recent paper on the length of the jump[20] has been supplemented by as yet unpublished experiments, has attempted to show the importance of the roller by replacing it with a fixed upper boundary and noting the resulting change in depth; Schoklitsch,[21] on the other hand, has analyzed the action of the roller from the viewpoint of regions of discontinuity (sources of turbulence) between the roller and the actual flow resulting in turbulent interchange of momentum.

The most recent departure from traditional research has been the endeavor of Engel[22] to study the jump as a three-dimensional phenomenon in the diverging section of a Venturi flume. It was by Engel that the Boussinesq number was devised, thus incorporating in a universal parameter characteristic of gravitational action a width term having no bearing whatever upon the force of gravity.

The authors have distinguished carefully between the significance of the Froude number and of the Reynolds number, stating that the Froude number is the correct criterion in cases of gravitational action only, and the Reynolds number in the case of viscous action only, and that it is practically impossible to obtain complete dynamic similarity if both viscous and gravitational forces are present to an appreciable degree.

It is quite possible that, in the past, the loss of energy accompanying the jump has been the indirect cause of the failure to consider the jump in terms of the Froude number, for the hydraulic engineer has become prone to think of energy loss as synonymous with conversion into heat, the latter being possible in fluids only through viscous action. Thus, it would seem at first thought that viscous forces are by no means negligible in the hydraulic jump. In fact, discrepancies between computed and measured values of depths are generally attributed to friction losses along the bottom and sides of the channel. Actually, however, such losses are probably extremely small over the short length of flow involved; the discrepancy arises rather from a failure to consider the velocity defect along bottom and sides in computing the true mean velocity head; it is a known fact that such failure may cause considerable error in measuring the actual energy of flow, in particular since this defect is exaggerated by such abrupt deceleration of flow as occurs in the jump.

Clarity in the matter of energy loss may be attained only through a revision of the impressions received in elementary courses in hydraulics. "Loss" of hydraulic energy is seldom synonymous with immediate conversion into heat energy; in fact, it is only in the case of pure laminar flow that such immediate conversion takes place. In turbulent flow through smooth pipes, for instance, similar direct loss occurs in the laminar boundary film adjacent to the pipe walls, but within the turbulent region the situation is quite different.

In the familiar Bernoulli theorem, the specific energy of flow is expressed as the sum of velocity head, pressure head, and elevation. What the theorem fails to include is a fourth term expressing the energy of turbulence, often of great magnitude, which the hydraulician has had as yet no means of measuring or of utilizing; this missing term should denote the kinetic energy of rotation, since the velocity head includes only the kinetic energy of translation. It is the conversion to this turbulent head which corresponds in large measure to the apparent energy "loss" caused by valves, "stilling" racks, abrupt changes in section, flow through rough pipes, and by the hydraulic jump. In each of these cases the hydraulic "loss" or formation of excessive turbulence is largely or entirely independent of viscous action. Although turbulence itself may be reduced in intensity only through viscous shear and accompanying conversion into heat, this latter process is by no means immediate, but on the contrary is extremely gradual. Hence it is that the resistance coefficient for rough pipes at high Reynolds numbers (where turbulence is caused by the action of the roughness projections) is a constant term, independent of changes in viscosity; for the same reason the energy "loss" or conversion from energy of translation into energy of turbulence in the hydraulic jump is practically independent of viscosity and hence is not a function of the Reynolds number.

Were it possible to express energy of turbulence as a fourth term in the Bernoulli equation, it would follow at once that the jump could be treated correctly by means of the energy principle, since the actual energy of the individual particles is practically unaffected by thermal loss during the short time of passage through the jump. It is to be remarked that the general problem of turbulent energy is of outstanding importance in modern fluid research.

The question of the part played by the surface roller should be quite clear once this conception of turbulence is understood. The roller is as indispensable a part of the direct jump as the turbulent wake caused by flow past a valve is an inseparable part of the function of the valve. Those who have observed carefully the behavoir of the roller through the glass walls of an experimental flume will recall vividly enough the fact that the roller is not the idealized, distinctly outlined region of flow shown schematically in illustrations, but an active participant in the diverging flow. In other words, no portion of fluid involved at any instant in the reverse motion of the roller remains in the roller for more than a brief space of time; instead, violently rotating masses of this roller are torn away constantly into the live stream below, this continuous process resulting in the high degree of turbulence—and hence of apparent loss—which is characteristic of the phenomenon.

It should be obvious that such recent expedients as omitting the roller from the physical analysis of the phenomenon or replacing it by a sloping upper boundary held in place above the flow are quite beside the point. On the other hand, although the roller is inseparably associated with the jump, its length is not a true measure of the jump itself; nevertheless, European experimenters have often located the apparent end of the jump by determining visually that point at which the reversal of surface movement terminates. It is to the credit of the authors that their analysis is particularly definite and correct in all these troublesome points.

SHERMAN M. WOODWARD,[23] M. AM. SOC. C. E. (by letter).—After reading such an admirable exposition of a multiplicity of involved mathematical relationships, one feels a necessity for trying to reduce the complicated series of consecutive steps to some logical system simple enough to be pictured in one's mind as an entity. To do this it is necessary to review all the steps of the discussion and to attempt to isolate the fundamental connecting bases.

The entire mathematical theory for the hydraulic jump in a horizontal frictionless rectangular channel is based on two fundamental equations which, using the author's notation, are:

$$V_1\, d_1 = V_2\, d_2 \qquad (24)$$

and,

$$\frac{\nu\, V_1\, d_1}{g}\,(V_1 - V_2) = \frac{\nu}{2}\,(d^2_2 - d^2_1) \qquad (25)$$

Equation (24) is commonly designated in hydraulics as the "law of continuity"; Equation (25) is a change-of-momentum equation, a form of Newton's second law of motion. In Equations (24) and (25): ν = density of the liquid; g = acceleration of gravitation; V_1 = velocity before entering the jump; V_2 = velocity after leaving the jump; d_1 = depth before entering the jump; and, d_2 = depth after leaving the jump. Considering ν and g as known constants, the other four quantities remain as variables. From Equations (24) and (25) any one of the four variables, as may be desired, may be eliminated. If V_2 is eliminated, for example, the commonly used formula for the jump is obtained:

---

[23] Cons. Engr., T.V.A., Knoxville, Tenn.

$$d_2 = -\frac{d_1}{2} + \sqrt{\frac{d^2_1}{4} + \frac{2\,V^2_1\,d_1}{g}} \quad \ldots\ldots\ldots\ldots\ldots (26)$$

In addition to the foregoing variables, the author introduces, among others, the following, all defined in terms of the original four:

$$q = V_1\,d_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

$$d_j = d_2 - d_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

$$d_c = \sqrt[3]{\frac{q^2}{g}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

$$\epsilon_{k1} = \frac{V^2_1}{2\,g} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

$$\epsilon_{k2} = \frac{V^2_2}{2g} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

$$\epsilon_1 = d_1 + \frac{V^2_1}{2\,g} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

$$\epsilon_2 = d_2 + \frac{V^2_2}{2\,g} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

and,

$$\epsilon_j = \epsilon_1 - \epsilon_2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34)$$

With Equations (24), (25), and (27) to (34), inclusive, it is possible, theoretically, to eliminate any nine of the twelve variables, giving 222 different equations, each containing three variables. Each of these equations can be solved for each of the variables and, therefore, can be written in three different ways, making a total of 666 possible equations, any of which may be used if one should so desire. (Actually, the number would be slightly less, due to the fact that some of the equations would contain only two variables.)

Unfortunately, an equation containing three variables cannot usually be represented graphically by a single line, or in any other equally simple manner. It can be represented by a surface, however, or in a plane by a family of lines. To handle an equation of three variables, then, it is a common device to divide by one of the variables, or reduce the variables to ratios, in such a way as, in effect, to reduce one of them to unity, thus obtaining an equation which can be platted as a single line. With twelve variables, ignoring reciprocals, sixty-six different ratios can be obtained, all of which can be used to swell to still greater numbers the list of possible equations. It would even be possible to extend the combinations further by taking ratios of ratios; but it is to be remembered, in contemplating such an endless series of mathematical gymnastics, that the entire mass contains no more knowledge than the two original equations and the definitions of the variables.

It is not extremely laborious to plot a family of curves; several families can be put on the same diagram; therefore, a few diagrams would suffice to introduce all the variables desired. However advantageous it may be to develop a large number of equations for purposes of research, of theoretical study, and of gaining an insight into the nature of the phenomenon, for the purposes of the practicing engineer, it seems desirable to adhere as closely as possible to the basic equations together with tables and diagrams to represent them.

ROBERT E. KENNEDY,[24] M. AM. SOC. C. E. (by letter).—It may be of interest to apply the data given in Table 1 to the formulas for length of the hydraulic jump suggested[25] by Donald P. Barnes, Jun. Am. Soc. C. E., who reports certain investigations made in Germany by Dr.-Ing. Kurt Safranez and quotes conclusions and formulas by Professor A. Ludin. The authors take issue with Dr. Safranez and contend that the jump is longer than that distance subtended by the visible roller as arbitrarily defined by him. Professor Ludin suggests an $\frac{L}{d_2}$-value of 4.5. The average of values in Column (4), Table 1, for the observed minimum length of jump divided by values in Column (3), for d_2, the down-stream water depth, happens to be exactly 4.5. The average for values in Column (5), the maximum length, divided by d_2 is 5.0 and ranges from 4.6 to 5.5 which is from 92 to 110% of the average. This is a span of 18 points. An $\frac{L}{d_2}$-curve is shown in Fig. 6.

Professor Ludin proposes a more accurate formula which may be derived from the following:

$$R = \frac{V_1}{V_c} \qquad (35)$$

and,

$$\frac{d_2}{L} = \frac{1}{4.5} - \frac{1}{6\,R} \qquad (36)$$

in which, in addition to the notation of the paper, R = a "flow index."[26] By combining Equations (35) and (36) and solving for *L*, the length of jump, a formula is obtained which, in the notation of Fig. 2, is:

---

[24] With Dept. of Investigations and Project Studies, U. S. Bureau of Reclamation, Denver, Colo.

[25] *Civil Engineering*, May, 1934, p. 262.

$$L = \frac{9\,d_2\,V_1}{2\,V_1 - 1.5\,V_c} \qquad (37)$$

in which V_c is the critical velocity obtained from Equation (4).

The results of applying the data in Table 1 to Equation (37) are shown in Table 2. The observed maximum length varies from 55% of the computed for the lowest ratio of $\frac{d_2}{d_1}$, in Column (12), Table 1, to 86% for the highest ratio. If the percentages in Column (7), Table 2, are plotted against the corresponding values of $\frac{d_2}{d_1}$, two curves may be drawn to indicate the approximate outside limits of the range of coefficients applicable to the Ludin formula and the discrepancy of this formula as based upon these data. Judging from these curves it appears to vary from 57 to 65%, or 8 points, for a $\frac{d_2}{d_1}$-ratio of 2.5 at the lower end of the curves and from 83 to 87%, or 4 points, for a $\frac{d_2}{d_1}$-ratio of 12 at the upper end.

* See Fig. 2. † From Column (5), Table 1.

For an illustration assume $d_1 = 0.36$ ft, $d_2 = 2.40$ ft, $V_1 = 17.2$ ft per sec, and $V_c = 5.7$ ft per sec. By the rough average approximation, $L = 5\,d_2$, the length is $5 \times 2.40 = 12.0$ ft. By Equation (27) $L = 14.4$ ft; or, applying the correction corresponding to a $\frac{d_2}{d_1}$-ratio of 6.7 which ranges from 82.5 to 86.5% and averages 84.5%, the length is equal to $14.4 \times 84.5\% = 12.2$ ft. In this case the "rough" approximation is not so rough!

L. STANDISH HALL,[26] ASSOC. M. AM. SOC. C. E. (by letter).—Designation of the component parts of the hydraulic jump in terms of a common parameter has reduced the characteristics of this phenomenon to a more readily understandable basis. The curves presented summarize the results of the experiments performed by the authors in a very concise manner. The differentiation between the use of the Froude and the Reynolds numbers is also notable.

With regard to the use of the results in engineering design, there are certain factors to be borne in mind which were not disclosed in the authors' experiments, which were made by producing a flow of high velocity by means of discharging water under a sluice. Flow of this type occurs from sluices in canals or from sluices at the toes of dams. A notable example of the latter is to be found in the flood-control dams of the Miami Conservancy District, in Ohio. Hydraulic jumps also occur at the bottoms of chutes, either in canals or on spillways from reservoirs. They also form at the toes of overflow dams.

In all cases where the flow of water is allowed to accelerate over a sufficient distance, air is mixed with the stream, and the phenomenon of "white water" occurs. The same admixture of air with water can be observed in waterfalls, or in natural stream channels, when the velocity is sufficiently high to draw air into the water by its agitation. Very few data appear to be available as to the volume of air which will become mixed with the water under these conditions. Such data as are available indicate that it is in proportion to the velocity; in other words, a velocity of 10 ft per sec would entrain 10% of air by volume and a velocity of 40 ft per sec would entrain 40% of air by volume.

The entrained air increases the bulk of the water near the bottom of a chute, or the apparent value of d_1 is increased. When this mixture strikes the pool at the foot of a chute, the agitation in the pool is greatly increased. In an open pool, it is not probable that the depth, d_2, is changed from the value normally expected, as the air is rapidly expelled. However, the length of the jump is materially increased, and it is usually found in practice that the length of pool as determined by the ordinary hydraulic formulas is inadequate. Additional free-board is also necessary at the bottom of the chute and in the pool, due to the great agitation of the water before the air is expelled.

More data are required for the design of such structures, both with regard to the volume of air entrained at high velocities and also with regard to the effect of the air on the hydraulic jump. Data on the first phase of the problem are rather difficult to secure by laboratory methods. It would appear that the velocity, the distance traveled, and the roughness of the surface of the conduit had some bearing.

However, data on the effect of entrained air on the hydraulic jump could be easily determined in the laboratory. In the experimental flume used by the authors, air could have been introduced in the bottom down stream from the sluice and the effect on the jump noted. It is hoped that the authors will be able to expand their experiments to cover this phase of the hydraulic jump. In the meantime, designers should increase the ratio of $\frac{L}{d_2}$ to values greater than 5 when conditions are such that it is to be expected that air will be entrained in the water above the jump.

[26] Chf. Hydrographer, East Bay Municipal Utility Dist., Oakland, Calif.

MORROUGH P. O'BRIEN,[27] ASSOC. M. AM. SOC. C. E. (by letter).—The preoccupation of engineers with the vertical elements of the hydraulic jump to the neglect of the horizontal dimensions is attributable to general amazement at the almost perfect agreement between theory and experiment as regards the depths and velocities involved. That so turbulent a phenomenon needed no "coefficient of ignorance" was both surprising and encouraging, and interest in it has helped greatly in advancing the application of the momentum principle to the solution of hydraulic problems.

One feature of the hydraulic jump which deserves attention is the fact that the equations apply to a frictionless liquid and yet a loss of energy is indicated. The theory provides no means of dissipating energy and one is left to assume that the energy at Point (2) in Fig. 2 is the same as at Point (1), but that a portion of it has become unavailable to cause further flow. The explanation appears to lie in the fact that although the sums of the pressure forces and dynamic reactions are equal and of opposite sign at the two points, the lines of application do not coincide and the fluid moving through the region of the jump is subjected to a continuously applied moment which superimposes a rotational velocity on the average velocity of forward motion. The energy involved in this rotational motion is the "loss" obtained from the combination of the momentum and energy equations. It should be emphasized that the mere existence of a surface "roller" could not cause this energy loss because little energy could be dissipated in the roller itself. However, if parts of this roller are continually torn away from it and pass down stream as vortices, the total energy lost is the summation of the energies of these vortices. In any real liquid, viscosity soon brings about the conversion of this macroscopic rotational energy into thermal energy. That the jump is not a reversible phenomenon in which the depth can decrease in the direction of flow from d_2 to d_1, which is possible from momentum considerations alone, is indicated by the impossibility of recovering this random thermal energy as energy of directed motion.

Another feature of the hydraulic jump which deserves more attention is the distribution of velocity in vertical sections, and the rapidity with which it approaches that resulting from friction alone. It does not appear to be safe to assume that, at the depth, d_2, the velocity distribution is normal for the reason that the highest velocities exist initially very near the bottom and there is no general criterion indicating the distance necessary for them to be reduced to a certain fraction of their initial intensity. It may be that a phenomenon occurs which is similar to "separation" along the blades of propeller pumps and turbines. Considering the layers immediately adjacent to the bottom, momentum and velocity must be lost at a rate sufficient to overcome both friction and the adverse pressure gradient and a point is reached at which the forward velocity is reduced to zero. The main stream may then separate from the bottom and pass over an eddy of sign opposite that of the surface roller.

---

[27] Associate Prof., Mech. Eng., Univ. of California, Berkeley, Calif.

In recent years, some difficulties have been encountered in the operation of hydraulic jump drops on irrigation canals. In these structures, the jump occurs in a pool at the bottom of an incline, and it may be that the usual pool length is not sufficient for the bottom velocities to be reduced to a safe value.

In most problems of open-channel flow, the energy and momentum curves can be computed from the average velocity (quantity divided by area), but where local conditions cause a considerable deviation from the normal velocity distribution, a correction factor must be applied to take into account the fact that the average of the momenta and energies transported across elementary areas exceeds the momentum and energy based on average velocity.[28] The authors assume that this correction factor is unity.

F. V. A. E. ENGEL,[29] ESQ. (by letter).—The investigations reported in this paper are of particular interest to the writer and they are a valuable contribution to the application of a dimensionless presentation of hydraulic test results in open-channel flow. In these days the application of the Reynolds number is a common occurrence in analyzing the frictional coefficient in closed conduits, the discharge coefficient of orifices and Venturi tubes, etc. Nevertheless, few papers deal with the specific problems of open-channel flow on that basis.

Several pages of the paper refer to "Theoretical Premises," which involve the Reynolds, Froude, and Boussinesq numbers. The remarks concerning the Reynolds number are quite consistent with the usual conception of that expression in hydraulic engineering, but the writer would like to suggest some modification of the sections on the Froude and Boussinesq numbers, especially as he feels himself responsible for introducing a term which has been called the "Boussinesq" number.

The kinetic flow factor, known as the Froude number, was applied for the first time in a similar form by Th. Rehbock in 1919 for the calculation of the head losses for water flow through bridge piers. This factor (see Equation (2)) is given as twice the ratio of the kinetic energy head to the potential energy head contained in each pound of liquid flowing at the depth, d. The velocity, V, is the mean velocity obtained by dividing the rate of flow through the cross-section of the stream. This expression certainly is very convenient and may also be sufficient in some cases; but Coriolis, de Saint Venant, and others have shown that it is often necessary to use a value which takes into account the velocity distribution over the cross-section. For such conditions the kinetic energy is greater than the kinetic energy based on the mean velocity,[30] and, therefore, Equation (2) becomes:

---

[28] "Velocity Head Correction for Hydraulic Flow," by M. P. O'Brien and J. W. Johnson, *Engineering News-Record*, August 16, 1934.

[29] Director of Research, Electroflo Meters Co., Ltd., London, England.

$$\epsilon = \epsilon_p + \epsilon_k = d + \frac{\alpha\ V^2}{2\ g} \dots\dots\dots\dots\dots\dots\dots (38)$$

in which α is greater than unity.

Equation (12), therefore, would become:

$$\lambda = 2\ \frac{\epsilon_k}{\epsilon_p} = \frac{\alpha\ V^2}{g\ d} \dots\dots\dots\dots\dots\dots\dots (39)$$

This expression, including α, would certainly be rather tedious to evaluate, and the reason for presenting it is mainly to show that the relations given by the authors are not quite as simple as they would indicate. They point out that "the hydraulic radius is related inherently with friction effect." In turn, the friction effect influences the velocity distribution and also the new term, α, in Equations (38) and (39). It seems quite reasonable to combine α and d in Equation (39) in such a manner that it becomes:

$$\lambda = \frac{V^2}{g\ \dfrac{d}{\alpha}}$$

and to replace the ratio, $\frac{d}{\alpha}$ (which has the dimensions of a length, but also takes into account the velocity distribution), by r', the hydraulic mean radius, obtaining Equation (18), the dimensionless quantity which has been called the Boussinesq number.

The writer has made extensive use of both the Froude and Boussinesq numbers in his present investigations on flow through side-contracted open channels (Venturi flumes).[31] The Froude number characterized a type of flow which is known as "free discharge." For a given rate of flow "free discharge" is defined as that condition under which the up-stream depth is unaffected, whatever the down-stream conditions may be.

The occurrence of a hydraulic jump could not always be determined by a "critical" Froude number. Rehbock[32] and other investigators also found that the "critical depth" had not yet been reached by the water level in the narrowest section of the contraction in spite of the appearance of surface rollers, which are commonly attributed to the presence of a hydraulic jump. Rehbock regarded this "partial change to rapid flow" ("Teilweiser Fliesswechsel") as being due to an uneven velocity distribution. In some section of the water stream, there is a sufficiently high velocity to produce a state of rapid flow.

The writer has analyzed[33] the expression which Professor Rehbock used to determine the first occurrence of a hydraulic jump. Rehbock's relation is a function of the Froude number and for that reason is not satisfactory to determine the change from streaming flow to rapid flow. The "critical" Boussinesq number was found to be more reliable over a wide range of flow to characterize the change from one type to another.[33]

[30] "Elemente der Technischen Hydromechanik," by R. v. Mises, Leipzig and Berlin, 1914, pp. 153–155.

[31] "Non-Uniform Flow of Water: Problems and Phenomena in Open Channels with Side Contractions," by F. V. A. E. Engel, *The Engineer*, Vol. 155 (1933), pp. 392 to 394; 429 to 430; and 456 and 457; and "The Venturi Flume," *The Engineer*, Vol. 158 (1934), pp. 104 to 107; and 131 to 133.

[32] *Zentralblatt der Bauverwaltung*, Vol. 39 (1919) pp. 197 to 200.

[33] "Venturi-Kanalmesser: Die messtechnischen Eigenschaften in Abhängigkeit von den Strömungsarten," by F. V. A. E. Engel, *Archiv für technisches Messen*, No. 45, March, 1935.

The attacks on the Boussinesq number seem to the writer to be relatively unfounded. Three different applications have proved the usefulness of this number. The practical engineer must judge the merits of a new expression, especially with regard to the extent to which it simplifies the presentation of hydraulic test results, even if the definite theoretical proof is not yet established.

In three cases the application of the Boussinesq number has been found to yield some simplification in presenting the following hydraulic features:

(1) The discharge coefficient of a Venturi flume in the range of rapid flow is a linear function of the Boussinesq number;[31]

(2) The dissipation of energy in the case of a Venturi flume for the "limit of free discharge" can be presented in a simplified way by plotting the ratio of the down-stream depth to the up-stream depth against the Boussinesq number for a section in the throat;[31] and

(3) The change from turbulent or streaming flow to rapid flow is given by a critical Boussinesq number which determines the first occurrence of a hydraulic jump.[33]

It would have been very interesting if the authors had published the different features of the hydraulic jump in cases where the up-stream depth, or the depth at the foot of the hydraulic jump, exceeds the hydraulic mean radius. From Table 1, the writer perceives that the investigators cease their investigations at a point where the depth at the foot of the jump exceeds the value of the hydraulic mean radius. Furthermore, in Fig. 3, some test results in the range of the undulating jump (that is, for values of the kinetic flow factor smaller than 3) would be of general interest.

BALDWIN M. WOODS,[34] ESQ. (by letter).—As one interested in fluid mechanics, although more especially in aerodynamics, the writer desires to endorse heartily the plan of attack followed in this paper and the presentation of results in generalized, dimensionless form through the aid of the principle of dynamic similarity. From practical considerations alone, the growing interchange of material between countries having differing systems of units, such as the English and the metric, makes it highly important to have results equally useful regardless of the basic system of units. Furthermore, as has been so often noted, the method of dynamic similarity causes one to give careful scrutiny to the variables involved and to the most significant simple combinations of these variables into coefficients or parameters.

There is also much to be said in favor of the tri-dimensional representation of the profile, as given in Fig. 9. Engineers generally need to cultivate familiarity with these three-dimensional presentations and facility in reading them. They are labor-saving devices, much simpler in actual use than the combination of several two-dimensional charts, which are otherwise necessary. The entire Engineering Profession is indebted to the authors for the elegance of treatment resulting from the discrimination exercised in selecting this form of presentation.

---

[34] Prof. of Mech. Eng., Univ. of California, Berkeley, Calif.

J. C. STEVENS,[35] M. AM. SOC. C. E. (by letter).—In presenting the results of their research on the length of the jump, the authors have made a most valuable contribution to hydraulics. They might have made a more happy choice of symbolism, however. The writer has found the notation, which follows Professor Bakhmeteff's book entitled "Hydraulics of Open Channels,"[36] quite a "hazard" in mastering this paper.

There are only two independent characteristics of the hydraulic jump, the initial depth and the initial velocity. From them are derived the initial energy head, the final depth, final velocity, the final energy head, the lost energy head, and the empirical characteristic—length. If these factors are expressed in terms of any other, a series of ratios is obtained which expresses the characteristics of the jump in dimensionless terms of dynamic similarity.

The authors have chosen the initial energy head as the denominator of their dimensionless terms. Mr. E. S. Crump[37] has expressed the jump characteristics in terms of Belanger's critical depth. Mr. G. A. M. Brown[37] has expressed them in terms of the lost energy head. The writer following Woodward[38] and others has chosen to express them in terms of the initial depth. Thus, the dimensionless terms, in reality, become jump dimensions for a unit initial depth. Viewed in this light, such a jump may for brevity be termed a "unit jump," and a far simpler conception of it is had by thinking of it as such than through any other set of dimensionless terms. There appears to be no advantage in the use of the "kinetic flow factor," λ, over the ratio of initial kinetic to potential energy. This ratio, $k = \frac{V_1^2}{2\,g\,d_1}$ (which equals $\frac{\lambda_1}{2}$), has the limiting value of 0.5 for critical velocity, which expresses the simple criterion for critical flow that, in any shape of channel whatever, the velocity head is one-half the mean depth.

The authors' height of jump, $d_j = d_2 - d_1$, in practical applications is quite inferior to the ratio heretofore used by Woodward and others, namely, $J = \frac{d_2}{d_1}$, particularly when dealing with jumps in channels other than rectangular.

---

[35] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

[36] Eng. Societies Monographs, McGraw-Hill Co., 1932.

[37] "The Standing Wave or Hydraulic Jump," *Publication No.* 7, Central Board of Irrig., Simla, India.

[38] Technical Repts., Pt. III, Miami Conservancy Dist.

The writer suggests the following simplified notation: Let d_1 = initial depth; d_2 = final depth; h_1 = initial velocity head; h_2 = final velocity head; E_1 = initial energy head = $d_1 + h_1$; E_2 = final energy head = $d_2 + h_2$; I = energy lost by impact and eddies = $E_1 - E_2$; and L = length of jump.

Then the following dimensionless terms apply in a "unit jump": $k = \frac{h_1}{d_1}$; $J = \frac{d_2}{d_1}$; $e_1 = \frac{E_1}{d_1}$; $e_2 = \frac{E_2}{d_1}$; $i = \frac{I}{d_1}$; and $l = \frac{L}{d_1}$.

In a rectangular channel, of unit width, the fundamental relationship applies:

$$J^2 + J = 4\,k \qquad (40)$$

which may be verified from Equation (16) by substituting $2k = \lambda_1$. The jump characteristics may now be expressed in terms of either k, or J, or both. Thus:

$$e_1 = k + 1 \qquad (41)$$

$$e_2 = J + \frac{k}{J^2} \qquad (42)$$

and,

$$i = e_1 - e_2 = \frac{(J - 1)^3}{4\,J} \qquad (43)$$

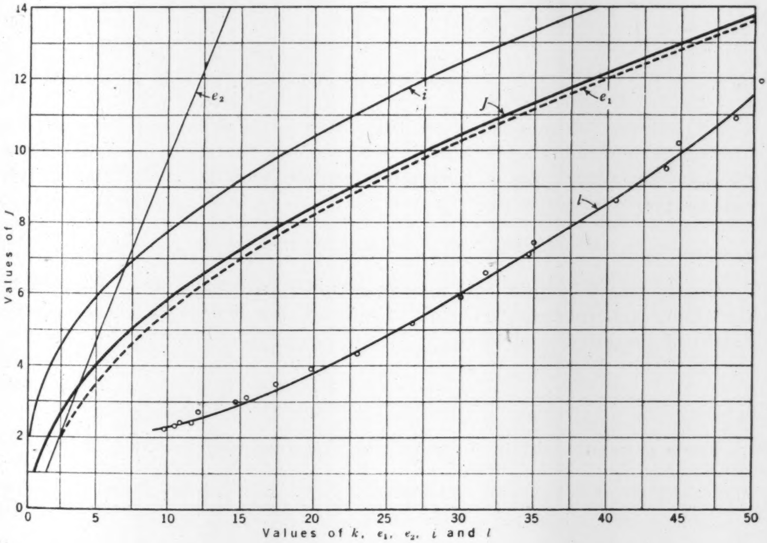

FIG. 10.

Fig. 10 shows the dimensionless characteristics of the unit jump in terms of either k or J. Curve J, as a function of k, is fundamental, and through it values of e_1, e_2, i, and l are found in terms of either k or J. The length is an empirical ratio obtained by averaging the values in Columns (13) and (14), Table 1.

It is significant to note in Fig. 10 that the characteristic curves are without points of maxima or minima. There is no maximum height of jump. The authors' maxima for d'_2 and d'_j, in Fig. 3, are not physical characteristics of the jump at all, but merely consequences of the terminology in which its characteristics are set forth. As a matter of fact these so-called maxima are for very low jumps: $d'_2 = 0.800$ for $\lambda_1 = 3$ corresponds to $k = \frac{3}{2}$ and $J = 2$, also $d'_j = 0.507$ at $\lambda_1 = 7.674$ corresponds to $k = 3.84$ and $J = 3.45$.

The advantage of the writer's terminology becomes apparent when expressions for the characteristics of the jump are desired for channels other than rectangular. Fig. 10, like Fig. 3, is applicable only to rectangular conduits and to unit widths. The fundamental relationships between J and k, however, may be found for a wide variety of conduits.[39] Once this relationship is found the other characteristics follow logically.

The general dimensionless formula for height of jump in a trapezoidal channel is:

$$J^4 + \left(\frac{5}{2}\,t + 1\right) J^3 + \left(\frac{3}{2}\,t^2 + \frac{5}{2}\,t + 1\right) J^2$$
$$+ \left[\frac{3}{2}\,t^2 + t - 6\,k\,(t + 1)\right] J - 6\,k\,(t + 1)^2 = 0 \quad \ldots\ldots(44)$$

in which $t = \dfrac{b}{s\,d_1}$; b = bottom width; and s = the side slopes (that is, s on 1); if the two side slopes are different, s is the average of the two. For a rectangular channel $s = 0$, and it can be shown that Equation (44) reduces to Equation (40). For a triangular conduit $b = 0$, and Equation (44) reduces to:

$$J^4 + J^3 + J^2 - 6\,k(J + 1) = 0 \quad \ldots\ldots\ldots\ldots\ldots(45)$$

Considering a conduit with a cross-sectional area that may be expressed by the exponential function, $a = K d^n$, in which K is a determinable constant, the height of the jump is given by,

$$\frac{J^n\,(J^{n+1} - 1)}{J^n - 1} = 2\,k\,(n + 1) \quad \ldots\ldots\ldots\ldots\ldots\ldots(46)$$

For a parabolic section, $n = \dfrac{3}{2}$, and Equation (46) becomes,

$$J^4 - (5\,k + 1)\,J^{\frac{3}{2}} + 5\,k = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots(47)$$

---

[39] "The Hydraulic Jump in Standard Conduits," by J. C. Stevens, M. Am. Soc. C. E., *Civil Engineering*, October, 1933, p. 364; also, discussion by G. H. Hickox, Jun. Am. Soc. C. E., *Loc. cit.*, May, 1934, p. 270. In these papers the ratio, r, is used instead of k. The latter is preferable and avoids the possibility of confusing it with the hydraulic radius.

In channels, the cross-sectional areas of which are segments of circles, a table of hydrostatic pressures is essential. Such a table and an explanation of its use in finding the height of the jump in circular conduits will be found in the writer's paper previously cited herein.[39]

In irregular channels the characteristics of the jump may be found graphically from the energy and momentum-plus-pressure curves as outlined[40] by Julian Hinds, M. Am. Soc. C. E.

All the foregoing expressions are dimensionless and for any given channel, involve only the two simple ratios, k and J, which are sufficient for the complete solution of the hydraulic jump. While the expressions are of many degrees, they are in effect single valued, since for every value of k there is only one value of J that will fulfill the physical conditions, and *vice versa*. Once k is known J is readily found by trial.

The writer questions the significance given to the "zone of undulating jumps" (Fig. 3). Fig. 7 shows a gradual transition from stable to undulating jumps as the ratio of kinetic to potential energy is diminished. Quite properly, the authors refrain from putting these results in terms of the initial energy because of the accelerations involved and the consequent departure from hydrostatic pressures, in the water prism.

In reality is not this "undulating jump" merely a "hang-over" from the oscillations that always accompany critical flow? At critical flow depths may vary considerably without appreciably changing either the energy or momentum-plus-pressure values. As a consequence the surface is in an unstable state and pronounced waves occur. For such conditions there is no jump, and in all the foregoing equations $J = 1$ and $k = \frac{1}{2}$ (the authors' $\lambda = 1$). If, now, the kinetic energy is increased and the potential energy is reduced ever so slightly (as, for example, by closing the sluice-gate) both k and J increase in value and a low jump occurs; but the flow is still barely removed from the critical, and the surface waves persist. These waves gradually fade away, as the ratio of kinetic to potential energy increases, and sensibly disappear for $k = 2$, say ($\lambda_1 = 4$). In reality, are there any valid grounds for stating that "the region near $\lambda_1 = 3$ is a zone of transition?" The range of undulations is for all values of λ_1 less than 4, and the less the value of λ_1 the greater the undulations. The point the writer wishes to bring out is that there appears to be no more reasons for setting up two kinds of jumps[41]—the "undular form" and the "direct form"—than for drawing a distinction between big jumps and little jumps.

The data on length of jumps are particularly interesting. The length expressed in terms of $d_2 - d_1$, varied from about 8 to 4.5, the latter value probably approaching a lower limit for which one may state that the kinetic energy expended can not cause the water to stand on a much steeper slope than 1 on 4. The upper limit, of course, is infinity for critical flow—at which there is no jump. The writer believes that for the sake of consistency the authors' ratio, $\frac{L}{d_1}$ (Table 1), is to be preferred, and this is the ratio given in Fig. 10.

---

[40] "The Hydraulic Jump and Critical Depth in Design of Hydraulic Structures," *Engineering News-Record*, November 25, 1920, p. 1034; see, also, the *M*-function, "Hydraulics of Open Channels," by Boris A. Bakhmeteff, M. Am. Soc. C. E., p. 232.

[41] "Hydraulics in Open Channels," by Boris A. Bakhmeteff, M. Am. Soc. C. E., Eng. Societies Monograph, 1932, p. 228.

The length of the jump must be the resultant of two motions: (1) The translatory motion of the prism down stream; and (2) the vertical motion due to the rate of conversion of kinetic to potential energy. The physical phenomena involved in this conversion are but little known. It appears that the greater the initial kinetic energy the more rapidly is this conversion effected; hence, the shorter lengths accompany the expenditure of the greatest amount of kinetic energy.

One practical value of these data is that now something tangible is available by which the length of the apron at the foot of overflow dams, and the spacing of baffles, can be determined rationally. Knowing the fall from forebay to apron, and the discharge, the initial depth on the apron is readily found. The height, and now the length, of the jump may be expressed in terms of this depth.

NOLAN PAGE.[42] JUN. AM. SOC. C. E. (by letter).—A research problem with which the writer recently had contact, involved a study similar in general to that presented by the authors, but resulted in values for length of jump sufficiently different to be of interest. This problem is one of several which have been and are under study by the Corps of Engineers, War Department, at the Hydraulic Laboratory, University of Iowa, Iowa City, Iowa, in connection with construction activities in the Upper Mississippi River and Ohio River Divisions.

FIG. 11.—MODEL OF STILLING-BASIN DESIGN.

As a step in the development of criteria for design for stilling-basins to protect navigation dams being built in the Upper Mississippi River, the simplified model shown in Fig. 11 was constructed and tested through a range of conditions indicated in Table 3. The model consisted of one Tainter gate and one-half of each supporting pier, built one-twentieth the size of the gates for Mississippi River Dam No. 20, and set up in a glass-sided flume. Instead of the designed sill and stilling-basin, a smooth, level, wooden floor was installed, as shown in Fig. 11. Water was supplied to the model through a 10-in. line from a constant-head tank two floors above the flume, passed through the apparatus as indicated, and discharged into a sump where it was re-pumped to the constant-head tank. Model quantities were determined by means of a rectangular, suppressed weir. Depths up stream from the model gate and down stream from the hydraulic jump were measured by vernier hook-gauges in stilling cans connected to the piezometers indicated in Fig. 11. Depths below the Tainter gate up stream from the hydraulic jump, were measured with a vernier point gauge.

Table 3 contains only those data taken in tests on this model which are pertinent to this discussion. The lengths of jump tabulated were measured directly in the model, taking the distance from the beginning of the jump, which was always sharply defined, to the point of highest rise down stream from the jump as observed through the glass sides of the flume. The accuracy of measurements has been indicated in the tabulation. It will be noted that the values, ϵ_1, in Table 3 are not computed from d_1, but were taken as equal to d_0, the height of pond-water surface above the temporary floor of the flume. This was considered more accurate than computing ϵ_1 because of the magnified effect of slight inaccuracies in measuring d_1. Theoretically, d_0 should have been corrected for velocity of approach and the resulting ϵ_0 for friction loss at the Tainter gate, but neither correction was made, the one tending to offset the other and each being small.

In an apparatus such as this model, in which the hydraulic jump expanded laterally as well as vertically, measured values of d'_2 could not be expected to follow the curve for a straight-sided channel given in Fig. 3. However, with the widths at Section (1) and Section (2) known, the lateral expansion could be taken into account in theoretical equations for height of jump. This was done for the model and resulted in the curve marked "d'_2, computed for model" in Fig. 12. Except in the range near the maximum height of jump, measured values fall very close to the computed curve. As was the case in the authors' tests, the range in which the departure of measured from computed values occurs was one of unstable flow. In some tests a standing wave condition alternated with a hydraulic jump, the alternations following an approximately equal period for a given model setting.

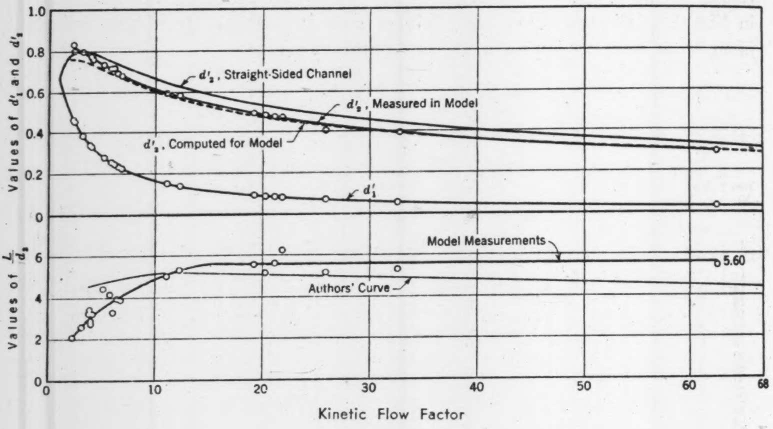

FIG. 12.

Lengths of jump measured in the model have been expressed as ratios of the depths down stream from the jump, and are plotted in Fig. 12. The authors' curve expressing the relation of this ratio to λ_1 has been transferred from Fig. 6 to Fig. 12 in order to compare directly the results obtained in the model with those obtained by the authors. It will be noted that, although the two curves assume a uniform slope at about $\lambda_1 = 14$, the authors' curve is below the curve drawn through model test points and slopes downward as λ_1 increases, whereas the model curve in this range was drawn with zero slope at a value of $\frac{L}{d_2} = 5.60$. It is thought that the jump may have been shortened in the authors' apparatus by friction on the sides of the narrow channel.

From the viewpoint of practical design, the abscissa, λ_1, involving the value, d_1, makes the curves of Fig. 12 awkward to use. Ordinarily, the known values from which dimensions for toe protection must be derived, are the quantity passing a dam site, the upper pool water-surface elevation, and the tail-water elevation corresponding to the quantity. When using the curves of Fig. 12, it is necessary first, to assume a value for d_1; from that, compute an elevation for the stilling-basin floor; and, then, compute by means of d_2, an elevation of tail-water surface, repeating the process until the computed and the given tail-water elevations agree. In this procedure, successive values of d_1 are not directly indicated by computed values of tail-water elevations.

A curve that is more directly useful as a means of computing stilling-basin floor elevations is that shown in Fig. 13. This curve was first called to the writer's attention by the late Floyd A. Nagler, M. Am. Soc. C. E., and was used in the design of Mississippi River Dam No. 2.[43] The abscissa in this case involves only the quantity per unit length of stilling-basin, which is readily determined from known river quantity and length of spillway, and the energy head up stream from the hydraulic jump, which may be taken as equal to the height of the pond-water surface above the stilling-basin floor. In using this curve, a stilling-basin elevation is assumed to provide data from which a basin elevation is computed, this process being continued until both elevations agree. Although trial and error methods must be used with this curve as with that of Fig. 12, computed and assumed values are directly related and converge rapidly. The basis for the abscissa of Fig. 13 is the equation for energy head at Section 1,

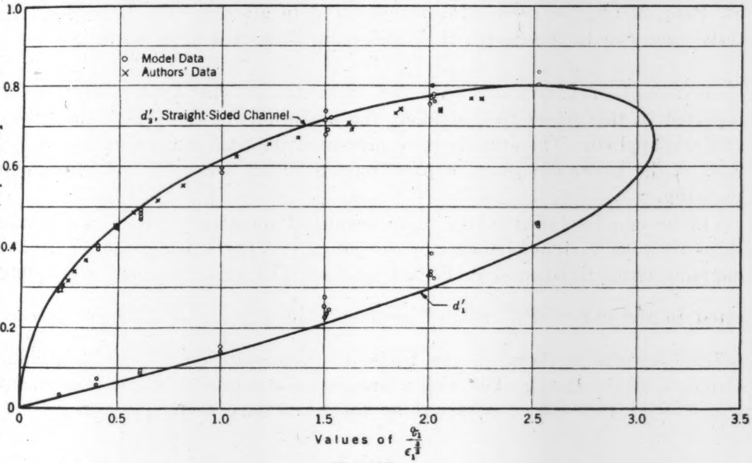

FIG. 13.

$$\epsilon_1 = d_1 + \frac{V_1^2}{2g} \qquad (48)$$

---

[43] "Laboratory Tests on Hydraulic Models of the Hastings Dam," by Martin E. Nelson, *Bulletin* 2, Univ. of Iowa Studies in Eng.

transformed to:

$$\frac{q_1}{\epsilon_1^{\frac{3}{2}}} = \sqrt{2\,g}\,\frac{d_1}{\epsilon_1}\sqrt{1 - \frac{d_1}{\epsilon_1}} \qquad (49)$$

The curve presented in Fig. 13 is open to criticism in two respects; First, the test results are not entirely consistent with it; and, second, the value, $\frac{q_1}{\epsilon_1^{\frac{3}{2}}}$, is not dimensionless. Nevertheless, Fig. 13 should not be rejected as inadequate because of this. If theoretical curves are used, and they are usually sufficiently accurate for design purposes, either Fig. 12 or Fig. 13 will give identical results.

Acknowledgment is made to the District Engineer, U. S. Engineer Office, St. Paul, Minn., for permission to use the data given in this discussion. The tests were run by Frederick S. Witzigman, Jun. Am. Soc. C. E.

ANDREI I. IVANCHENKO,[44] M. AM. SOC. C. E. (by letter).—The results reported in this paper fully confirm the usefulness of the general methods of analysis applied. The authors have presented the first comprehensive explanation of the hydraulic jump, a phenomenon which was once considered quite puzzling.

Little can be added to the clear graphical representation of the relationships between various elements of the jump, and particularly the longitudinal characteristics illustrated in Figs. 6 and 9. The writer is particularly interested in the curve of $\frac{L}{d_j}$ plotted against λ in Fig. 9. This curve was considered by the authors as the basis of their solution of the longitudinal elements of the jump. The writer proposes the following expressions for the equation of this curve, obtained by the customary method:

$$\frac{L}{d_j} = 10.6\,\lambda^{-0.185} \qquad (50)$$

or, solving for L,

$$L = 10.6\,d_j\,\lambda^{-0.185} \qquad (51)$$

in which $d_j = d_2 - d_1$, or,

$$L = 10.6\,(d_2 - d_1)\,\lambda^{-0.185} \qquad (52)$$

Equation (52) is quite simple, being derived from experiment; and, assuming that it is based on methods of approach that are physically correct, it is more justified than any other known formula for the length of the jump. In fact, the length of the jump is doubtless the function of the height of the jump (d_2 — d_1), and the state of flow, which is represented by λ, the kinetic flow factor.

---

[44] Civ. Engr.; Assoc. Prof., Hydraulics and Water Power Eng., Industrial Inst., Novocherkassk, Union of Socialistic Soviet Republics.

The writer has checked the values of the ratio, $\frac{L}{d_j}$, by means of Equation (50) for all values of λ taken from Table 1. The results are given in Table 4.

TABLE 4.—CHECK COMPUTATIONS OF THE RATIO, $\frac{L}{d_j}$

26	9.90	6.63	7.03	6.936	6.94	33	74.56	4.65	5.17	4.774	4.80
29	11.87	6.73	7.13	6.710	6.70	38	78.69	4.24	5.10	4.727	4.72

The writer is fully aware that the data in Column (6), Table 4, indicate certain discrepancies. However, obviously, as the authors state, the tracing of the curves was carried out so "that they must pass within the plotted ranges, indicating the possible range of the *L*-values." For all the curves of Fig. 6 the range of *L*-values from Runs Nos. 25 and 45, as well as for Run No. 28, lies below the curves. This may indicate some degree of unreliability in the experimental data for these runs, because the proposed formula, Equation (50), agrees very well with experimental data in all other cases.

F. T. MAVIS,[45] ASSOC. M. AM. SOC. C. E., and ANDREAS LUKSCH,[46] ESQ. (by letter).—The authors' observations of the length of the hydraulic jump in a narrow channel are a welcome addition to the literature of hydraulic research. The transfer of data from the model tests to the prototype should be made with caution, however, in the light of the authors' statement (following Equation (15)) that "in analyzing open-flow cases * * * the principle [of similitude] in general may be applied to geometrically similar cases only."

Referring to Equations (16) and (17) presenting the theory of the hydraulic jump the authors state that these equations "apply equally to a jump at the foot of the Boulder Dam and a small-scale model in a laboratory flume." It should not be overlooked, however, that in the derivation of these equations the effects of channel friction are wholly neglected. It is not unreasonable that the height of the jump should be little affected by boundary friction, and that a well-defined relation should exist between depths of flow at alternate stages. The location at which the jump occurs in a level channel of rectangular cross-section can be changed, however, by seemingly insignificant changes in resistance to flow. For a given depth of flow and a given kinetic flow factor it seems reasonable that the length of jump in a narrow channel would be less than in a channel relatively much wider, even if the side walls of both channels were made of glass. Due to the effects of the side walls the length of the hydraulic jump in a narrow channel may be relatively less than in a wide channel. Further tests are needed to show what effect the relative width of a channel may have upon the length of the hydraulic jump under otherwise similar conditions.

---

[45] Assoc. Director in Charge of Laboratory, Iowa Inst. of Hydr. Research; Prof. and Acting Head of Dept. of Mechanics and Hydraulics, The State Univ. of Iowa, Iowa City, Iowa.

[46] Research Asst. Engr., Iowa Inst. of Hydr. Research, State Univ. of Iowa, Iowa City, Iowa.

On the basis of tests conducted for the Miami Conservancy District, Riegel and Beebe[47] stated that,

> "The length of the jump is approximately five times its height. While the beginning of the jump is fairly definite, its lower end is indefinite, and this figure represents merely a general estimate. The lower end was taken as the place where the water surface became and remained sensibly level, a place which was variable in position and difficult to locate."

In 1927, Safranez[48] studied the hydraulic jump experimentally at the Technische Hochschule in Berlin, Germany. The tests were conducted in a glass channel 19.6 in. wide. Lengths of jump were reported[49] for eighteen tests in which the kinetic flow factor, $\lambda_1 = \frac{v_1^2}{g\, d_1}$ varied from 3 to 365, lengths of jump from 1.0 to 3.3 ft, and heights of jump from 0.18 to 0.76 ft. Safranez proposed a tentative formula for the length of the jump which, using the authors' symbols, reduces to:

$$L_j = 6\, d_1 \sqrt{\lambda_1} \ldots\ldots\ldots\ldots\ldots\ldots (53)$$

An analysis of these data[49] for kinetic flow factors less than 80 (the range reported by the authors in Table 1), showed that the simple formula:

$$L_j = 5.2\, d_j \ldots\ldots\ldots\ldots\ldots\ldots (54)$$

was in better agreement with the observations than Equation (53). The observed ratios, $\frac{L_j}{d_j}$, for the nine tests ranged from 4.6 to 5.5 and the mean absolute error in calculated lengths of jump, using Equation (54), was 6 per cent. For kinetic flow factors greater than 80 the length of the jump was 4.5 times its height, ranging from 4.0 to 5.1 for nine tests, with a mean absolute error of 5 per cent. The question naturally arises whether this general reduction in the ratio, $\frac{L_j}{d_j}$, for higher values of λ_1 may not be due to the resistance offered by the side walls and whether the ratio might not be substantially constant for a wide channel?

[48] "Untersuchungen ueber den Wechselsprung," von Kurt Safranez, *Der Bauingenieur*, v. 10, Heft 37, p. 38 (1929).

[49] *Loc. cit.*, Table 4.

As a part of a general study of stilling pools below spillways, tests were made at the Iowa Institute of Hydraulic Research to determine the geometrical properties of the hydraulic jump. The tests were conducted in a rectangular flume, 26 in. wide, lined with galvanized sheet metal. Water flowed under a sluice-gate with a rounded lower lip upon a level apron of steel plate and smooth cement mortar. The rates of flow varied from 0.48 to 1.44 cu ft per sec per ft width of channel, the depths of flow above the jump, from 0.05 to 0.15 ft, and the heights of jump, from 0.22 to 0.73 ft. In these tests the length of jump varied from 1.4 to 4.5 ft. Fig. 14(*a*) summarizing the data, shows as ordinates the ratio of length to height of jump and as abscissas, the kinetic flow factor. Fig. 14(*b*) shows as ordinates the ratio of length of roller to height of jump. An analysis of the tests conducted in a flume, 26 in. wide, indicated that the length of jump was approximately equal to 6.2 times its height and that the length of roller was approximately equal to 5.2 times its height.

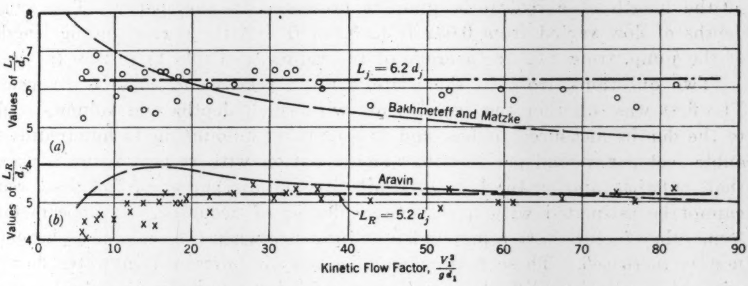

FIG. 14.—SUMMARY OF OBSERVATIONS, LENGTH OF HYDRAULIC JUMP.

V. J. Aravin[50] has presented a semi-rational analysis for determining the length of the hydraulic jump in which he followed the suggestion of Professor M. A. Velikanov "to divide the stream, when computing the losses, into two regions: dead zones, where only rotatory motion of the liquid is taking place, and zones where progressive motion is observed." Empirical coefficients were obtained from tests by Bakhmeteff, Pietrkowski, Safranez, Einwachter, and Aravin. The results obtained by the simplified formula suggested by Aravin, are:

$$\frac{L}{d_c} = 0.33\,A\,\frac{(\xi_2 - \xi_1)^3\,\xi^2_1}{\xi_2} \qquad \ldots\ldots\ldots\ldots\ldots\ldots(55)$$

---

[50] "The Determination of the Length of the Hydraulic Jump", by V. J. Aravin, *Transactions*, Scientific Research Inst. of Hydrotechnics, Vol. 15, pp. 48–57 (1935). (Translated from the Russian by Andreas Luksch.)

in which L = length of the hydraulic jump (roller); d_c = critical depth; $A = 0.54\,\xi_2^{4.35} + 75$; $\xi_2 = \frac{d_2}{d_c}$; $\xi_1 = \frac{d_1}{d_c}$; and d_1 and d_2 = depths of flow above and below the jump, respectively.

These data have been re-arranged for purposes of comparison and are shown in Fig. 14(*b*). Within the range of kinetic flow factors included in the authors' tests the ratio, $\frac{L_j}{d_j}$, which follows from Aravin's analysis may be replaced by a constant value, 5.4, with a mean absolute error of approximately 5 per cent.

I. M. NELIDOV,[51] ASSOC. M. AM. SOC. C. E. (by letter).—A graphical interpretation of the experimental results pertaining to the determination of the length of a hydraulic jump is presented in this paper. The actual depths of flow varied from 0.032 ft to 0.253 ft and the corresponding lengths of the jump, from 1.62 ft (average of the values in Table 1) to 2.50 ft.

Two questions arose in the writer's mind relative to these experiments. The first was, whether the experiments with small depths and volumes apply to the depths measured in feet and to quantities amounting to hundredths of cubic feet per second per second. The situation with respect to weirs shows that, notwithstanding the laws of similarity, the discharges of full-sized weirs cannot be estimated with a reasonable degree of accuracy. It appears that some other factors have a preponderant influence when the scale of a phenomenon is increased. These factors may be the air entrained in water flowing with high velocity, different roughness conditions, pulsation of flow, assymmetry in conditions of approach, and, perhaps, some others.

Another question was whether it is entirely correct to designate as the length of a jump—the length of its top roller, which ordinarily is longer than the length of the transition from one stage to another. For the most part, the surface curve of this transition is concave upward and only near the conjugate depth, d_2, does it acquire a sharp curvature concaved downward.[52] This indicates that the velocities of a high order may occur farther down stream than is ordinarily anticipated.

As a matter of reference the writer wishes to mention a study made by V. J. ARAVIN[53] based on the theorem of Bernouilli and using the computation of losses occurring in the top roller as a means for determining its length. The results were plotted on a curve for $\frac{d_2}{d_c}$ against $\frac{L}{d_c}$, L being the length of the roller, for the limits, 1.5 to 3.5 and 0.4 to 1.6, correspondingly. This curve agrees well with the experiments by Bakhmeteff, Pietrowsky, Safranez, Einwachter, and Aravin, plotted on the aforementioned curve.

[53] "The Determination of the Length of a Hydraulic Jump", by V. J. Aravin, *Transactions*, Scientific Research Inst. of Hydrotechnics, Vol. XV, Leningrad, 1935.

BORIS A. BAKHMETEFF,[54] M. AM. SOC. C. E., AND ARTHUR E. MATZKE,[55] JUN. AM. SOC. C. E. (by letter).—The many sided and helpful discussions prompted by the paper are gratifying. The endorsement of the manner of treatment by Professor Woods and the appreciative remarks with regard to its practical usefulness by Mr. Stevens are ample reward for the efforts of the writers to clarify a complex and, at times, puzzling field of study. Many new questions have been raised which cannot be answered adequately in the light of the knowledge available at present and which, therefore, usefully indicate subject matter for further research.

The writers are fully conscious of the limitations imposed on the results by the size of the flume. They agree entirely with the remarks by Messrs. Mavis and Luksch, Nelidov, and others regarding the possible effect of the channel dimensions on the friction and the longitudinal dimensions of the jump. In fact, final clarity on this subject can be obtained only through systematic and well-planned observations on a scale exceeding any of the experimental work heretofore cited. Furthermore, in comparing observations, it will be imperative in the future to adopt some unified basis in determining "the end of the jump." In fact, some of the discrepancies suggested by Fig. 13 and Fig. 14 may be partly due to differences in estimating where the jump terminates.

The uncertainty of all these features would seem to militate, at least for the time being, against any premature attempts to crystallize the available knowledge in that, or in any other empirical, formula for computing the length of the jump (such as those suggested by Professor Ludin, and referred to in Mr. Kennedy's discussion; the formula proposed by Professor Ivanchenko, Aravin, etc.).

The writers further appreciate the possible effect of "white water", as indicated by Messrs. Hall and Nelidov. This is also a question that can be answered only by special experiments. However, one should bear in mind that the basic formulas, Equations (8) to (17) do not carry, explicitly, the value of the specific weight, γ. Therefore, it would seem that presence of air in itself should not substantially affect the numerical relations in the jump, provided the average contents of air throughout the jump is not changed.

Any possible effect of the size of the streaming, to be considered eventually in practical engineering computations, will be limited to longitudinal elements only. As justly emphasized by Professor O'Brien, the vertical elements observed, even in the smallest flumes, are in such marvelous agreement with the theoretical curve, that scarcely any further "correction" is necessary. This fact would seem to justify the practical usefulness of Equations (8) and (16) and of dimensionless diagrams of the type of Figs. 3, 10, and 12, in their simplest form, without introducing any possible corrections, as mentioned by Professor O'Brien and Dr. Engel, to take into account the unevenness of the velocities and their actual distribution in the cross-sections. This correction, as established by Coriolis[56], requires multiplying the average velocity group in the momentum equation, $\frac{\gamma}{g}\ Q\ V = \frac{\gamma}{g}\ A\ V^2$, by a correction factor, $\alpha = \frac{\int v^2\,dA}{V^2 A}$; and in the energy equation the group, $\frac{\gamma}{g}\ Q\ \frac{V^2}{2} = \frac{\gamma}{g}\ A\ \frac{V^3}{2}$, by a factor, $\alpha' = \frac{\int v^3\,dA}{V^3 A}$, in which the respective integrals represent a summation over the entire area of the cross-section. The French hydraulicians of the Nineteenth Century gave much consideration to these points. Boussinesq in particular sanctioned the use of an average factor of about $\alpha' = 1.1$ and $\alpha = 1.03$. These numerical values were abstracted from observations on fully established, uniform flow patterns in canals and circular conduits. Now, flow in the section preceding the jump, where the kinetic energy is at its highest, usually follows a zone of intense acceleration (such as below a sluice or at the bottom of a spillway), the effect of which is to straighten out the velocities of the different filaments and to bring the velocity pattern in the lower-stage section before the jump close to practical uniformity. In the upper-stage section the influence of the kinetic energy is comparatively slight. However, to obtain some idea of the velocity picture in this region, special experiments were made in the Fluid Mechanics Laboratory of Columbia University, in New York City, the results of which are shown in Fig. 18. The velocity variance does not seem to be excessive.

[54] New York, N. Y.

[55] New York, N. Y.

From the discussions by Messrs. Stevens and Page it would appear that dimensionless unified diagrams of the type of Figs. 12, 10, and 3, have become the order of the day. The value of such generalized diagrams lies exactly in eliminating the needless "series of mathematical gymnastics", so strongly objected to by Professor Woodward. There is no essential difference between the diagrams of Fig. 3 and those given by Mr. Stevens (Fig. 10) and Mr. Page (Fig. 12). Obviously, a relationship that exists between certain interdependent factors in a jump can be depicted equally well by selecting any of the factors that enter the problem as the independent variable against which all the other elements are plotted.

The choice of that or some other independent variable as a basis is largely a matter of taste and individual preference. The writers prefer λ, as in Fig. 3, or $d'_1 = \frac{d_1}{\epsilon_1}$[57], because the presentation in this case happens to be in direct and organic relation to the practical means of obtaining a jump as illustrated in Fig. 2. It is precisely for this reason that the curves in Fig. 3 indicate certain important physical features, which are entirely eclipsed in Fig. 10, or which can be derived from Fig. 12 only by indirect inference. The first is the course of d_j and its maximum value. Mr. Stevens takes exception to the notion itself, by stating: "There is no maximum height of jump * * *. The authors' maxima for d'_j and d'_2 in Fig. 3, are not physical characteristics * * * but merely consequences of the terminology * * *". This is a point of substantial importance. Obviously, the writers failed to make the matter sufficiently lucid. There is no better means of clarifying a point than by direct observation. Therefore, a special experiment was made using a layout similar to Fig. 2. The height, H, was kept constant and equal to 1.402 ft. The sluice-opening was changed, increasing the depth, d_1, and the discharge. By regulating the tail-water the jump was maintained in position near the sluice. With varying discharges, the lower and the upper stage depths (and thus the height of the jump, d_j) were measured. The data are assembled in Table 5.[58] As noted in Fig. 15 the height of the jump first increases until it reaches a maximum value at $d_1 = 0.27$, after which d_j decreases. The value of $\frac{d_1}{H} = \frac{0.27}{1.4} = 0.193$ accords very closely with the theoretical value of $d'_1 = 0.206$ corresponding to $\lambda = 7.67$, at which the maximum is supposed to occur.

Mr. Stevens further questions the significance of the zone of undulating jumps which, as the writers claim, corresponds in Fig. 3 to the zone of the mounting d'_2-curve between $\lambda = 1$ and the maximum at $\lambda = 3$. The writers fully appreciate the potency of Mr. Stevens' remarks about the undulatory form of motion in the vicinity of the critical depth in general. However, they cannot escape the feeling that the undulatory jump is a separate and well determined phenomenon in itself. Strangely, it was the undular jump

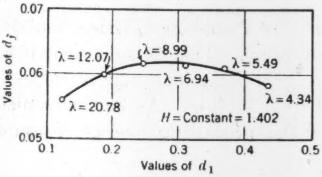

FIG. 15.

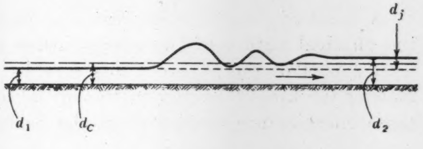

FIG. 16.

---

[58] In Table 5, H = constant = 1 402 ft.

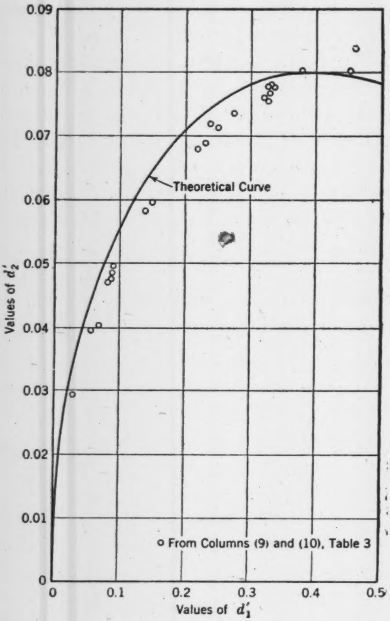

FIG. 17.

that was observed and described by most of the earlier investigators, for the simple reason that they worked with jumps that occurred in channels of steep slope, where flow in uniform motion was in a sub-critical (rapid) state. Compared to conditions at the foot of a dam or below a sluice the kineticity in uniform rapid flow is comparatively small, usually being far from sufficient to bring the jump into the direct roller form characterized by $\lambda \geq 3$ and $d'_1 \leq 0.4$. A schematic representation of an undulatory jump is given in Fig. 16. What differentiates these jumps from undulatory motions in the vicinity of the critical depth is the very substantial difference between the upper and lower stage, the depth ratio at times approaching the theoretical limit of $\frac{d_2}{d_1} = 2$.[59]

A distinct feature of the undular jump is the fact that, due to the curvature of the streaming, the momentum equation ceases to apply, and that observed values of d_2 are in excess of values computed from Equations (8) and (16).[60] This fact is confirmed once more by Mr. Page's observations. In fact, plotting the d'_2-values from Table 3 against d'_1, one arrives at Fig. 17. The points in the zone of direct jumps ($d'_1 < 0.4$) follow the theoretical curve rather satisfactorily, whereas the points for $d'_1 > 0.4$ fall outside the curve.

A point of particular interest is emphasized by Professor O'Brien, namely, the physical nature of the energy losses in a jump. The thought is that at least a part of the apparent loss may be due to a fallacious manner of estimating the kinetic energy in the initial and final section. As matters stand, these energies are computed on the basis of the prevailing average forward velocities $\left(\frac{V^2_1}{2g} \text{ and } \frac{V^2_2}{2g}\right)$, whereas it does stand to reason that at the upper stage, in addition to the average forward velocity, there might possibly be a substantial rotational effect. The senior writer is frank to admit that for a time he was disposed to attribute a considerable influence to this fact. He remembers having stated such views in informal discussions with members of the profession. Basically, the question reverts to the form of the velocity curve in Section d_2. To make the matter clear, at least qualitatively, special experiments were made at Columbia University which are illustrated by Fig. 18. By means of a Pitot tube, velocity diagrams were obtained in the respective cross-sections corresponding to the "end of the jump"; then, a foot up stream nearer the roller, and, finally, down stream at a distance of $3\frac{1}{2}$ ft, where tranquil flow was unquestionably re-established. In the curves as given, the abscissas represent the combined pressure and velocity heads registered

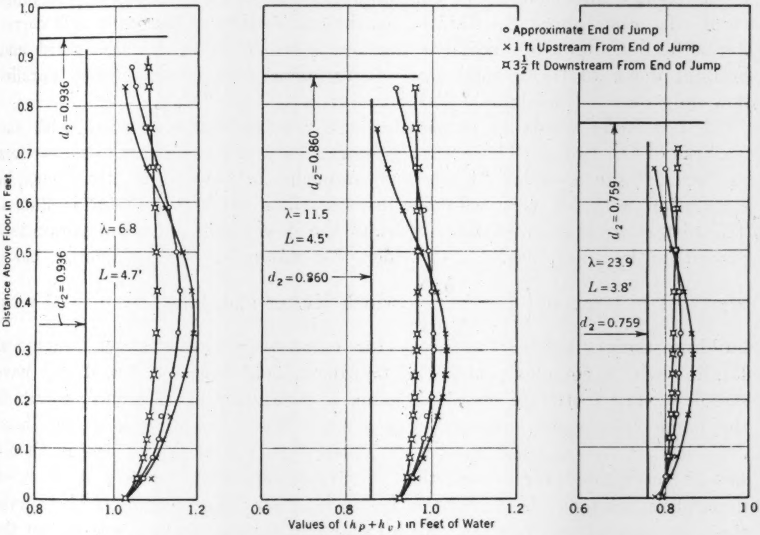

FIG. 18.

by the Pitot tube and referred to the bottom of the flume. The pressure head, corresponding to hydrostatic distribution at the end section, with h_p assumed equal to d_2, is given by the d_2-vertical. Invariably, a certain relative rotation in an anti-clockwise direction is present in the "end-of-the-jump" section. This rotation is entirely eliminated $3\frac{1}{2}$ ft down stream. The rotation is relatively larger at small values of λ, and much less noticeable at the highest values of λ, where the loss of energy should be the greatest. Although these experiments are of a preliminary nature and must be substantiated by more detailed work, they would seem to testify against attributing any too great influence to relative rotation. It would seem that the correct explanation of the loss is that given in the discussion by Mr. Rouse. When expressing the kinetic energy in terms of the average forward velocity, one neglects the fact that a considerable portion of initial energy is absorbed by the kinetic energy of the additional turbulent agitation, which can be symbolized mathematically thus:

$$\Sigma \rho \frac{1}{2} [(u')^2 + (v')^2 + (w')^2] \; dx \, dy \, dz \ldots\ldots\ldots\ldots (56)$$

in which u', v', and w' are the local turbulent velocity components, variable in time and space, whereas the summation must be taken over the entire volume of the jump. As Mr. Rouse points out, the final molecular absorption of this energy occurs in the form of heat created by the additional viscous friction caused by excessive turbulent agitation. Obviously, such viscous friction is not limited to the average forward motion and is greatly intensified at every point by the presence of turbulent components complementary to the average motion. There is every reason to believe that the dissipation of this superfluous energy into heat is not consummated within the confines of the jump itself. In other words, the fluid leaves the end section of the jump still carrying a high content of excessive turbulence which is finally dissipated and brought down to the normal state of turbulent loss in established parallel flow only over a considerable distance.

A few more words of elucidation are required in connection with the remarks of Dr. Engel. There was no desire whatever on the part of the writers to "attack" the so-called "Boussinesq number" introduced by Dr. Engel in connection with his very valuable investigations of flow in Venturi flumes. The history of hydraulics shows that in the past many empirical parameters proved to be most useful. Consider, for example, the parametric basis, expressed in terms of $\left(a + \frac{b}{\sqrt{R}}\right)$, which Kutter and, later, Bazin used when building their empirical formulas for estimating open-channel roughness. Dealing with a complex problem of tri-dimensional flow, Dr. Engel may have struck a very fortunate chord in using a parameter of reference, to which the name "Boussinesq number" was given. What the writers believe, however, is that an empirical factor, no matter how practical and useful, should not be interpreted for a condition it cannot represent—namely, a mark of dynamic similarity. If the writers understand Dr. Engel correctly he believes that, in view of the friction effect (which is disregarded in setting up the customary momentum equation for the jump, but which, obviously, is nevertheless present), jump data can be systematized more adequately by referring them to the Boussinesq number instead of using as a base the kinetic flow factor (or Froude number). In Dr. Engel's opinion this should become particularly evident in jumps where the depth at the foot of the jump exceeds the hydraulic mean radius.

To clarify this interesting question a special narrow channel, 2 in. wide, was built into the regular flume and a series of jumps was observed. The data are presented in Table 6.

TABLE 6.

Run No.	d_1	d_2	$\frac{d_2}{d_1}$	λ	R	$\frac{d_1}{R}$
N–1..........	0.222	0.764	3.44	9.31	0.0619	3.58
N–2..........	0.133	0.671	5.05	17.01	0.0522	2.55

N–4..........	0.048	0.442	9.22	52.30	0.0308	1.56

As seen, the ratio of the initial depth to the hydraulic radius reaches $\frac{d_1}{R} = 3.58$; nevertheless, the experimental points in Fig. 19 do not deviate much from the theoretical curve. To clarify the matter further a still more direct experimental proof was sought. By appropriately varying the discharge and the initial depth, d_1, it was attempted to obtain a series of jumps at practically identical values of λ, but with substantially varying Boussinesq numbers. If the contention of Dr. Engel were correct, the observed data referred to λ would scatter. On the other hand, when plotted against B (see Fig. 20), the points should manifest better regularity. The runs marked in Table 7 by the letter, C, were observed in the 2-in. flume with a value of λ actually varying between 7.93 and 7.56, or a variation of 5%, whereas the Boussinesq

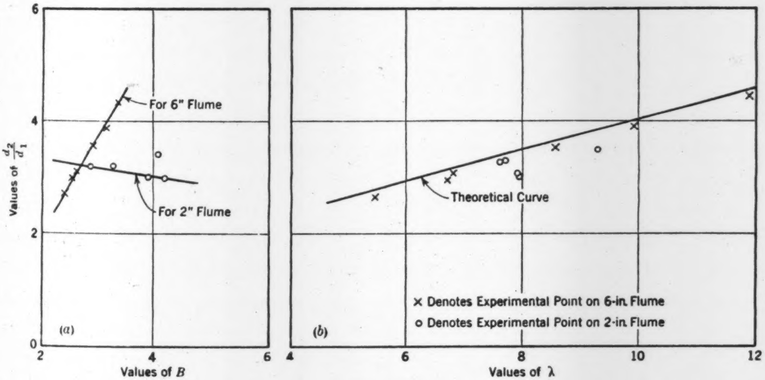

FIG. 20.

number varied about 36 per cent. Obviously, friction makes itself felt, but the observed ratios, $\frac{d_2}{d_1}$, form a compact group, with a variation of 7 per cent. For further clarification Table 7 contains certain data, obtained at neighboring values of λ on the 6-in. flume, as given in Table 1. All the observed data when referred to λ, range quite consistently close to the theoretical curve in Fig. 20. By contrast, when referred to the Boussinesq number, the points for the 2-in. flume and the 6-in. flume form two separate and incompatible curves.

Paper No. 1936

FRICTIONAL RESISTANCE IN ARTIFICIALLY ROUGHENED PIPES

By Victor L. Streeter,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. Warren E. Wilson, Richard G. Folsom. Ralph W. Powell, and Victor L. Streeter.

Synopsis

The flow of fluids in smooth pipes is so well understood that the losses due to friction may be predicted to within 5 per cent. The problem of estimating friction losses in old pipes, or in those roughened by use, however, has been inadequately solved. In order to clarify the problem completely much study and experimentation are necessary. This paper, which is an effort in that direction, presents the results of an experimental investigation of frictional resistance in artificially roughened pipes. It has been undertaken in an effort to show, qualitatively, the effect on the friction factor of certain artificial irregularities—varying in shape and size—that were introduced in pipes used for the tests. With water as the fluid, loss of head was investigated for roughened, 2-in., brass pipe, the Reynolds numbers ranging from 20 000 to 1 250 000. The roughness elements consisted of grooves cut spirally into the pipe. The degree of roughness was varied by changing the depth, shape, and number of grooves per inch.

The loss of head due to friction was found to increase with an increase in the depth of the grooves, provided the same general shape was maintained. The shape of the grooves, however, seems to have almost as much affect on the loss of head as the depth. The experiments also indicate that the roughness elements may be placed so close together that the loss of head is reduced. The work of previous investigators is summarized briefly; the apparatus, preliminary experiments, experiments for obtaining data, and computations are described; and the results of this investigation are discussed.

Note.—Published in February, 1935, *Proceedings*.

NOTATION

The symbols in this paper are introduced in the text as they occur and are summarized for reference in Appendix I. An effort has been made to conform essentially with "Symbols for Hydraulics,"[2] compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1929.

PREVIOUS INVESTIGATIONS

Investigations of fluid flow in pipes have been concerned with the development of general formulas, and, more recently, with studies into the effect of artificial roughness on the friction factor.

General Considerations of Fluid Flow.—In the evolution of formulas dealing with the flow of fluid in pipes, the findings of Hagen, Poiseuille, Darcy, Reynolds, and Blasius are especially significant. In 1839, Hagen[3] observed that there were two different types of fluid flow through pipes, now commonly designated as stream-line and turbulent flow. Thirty years later he stated that the point at which transfer from one form of flow to the other occurred depended on the radius, the velocity, and the temperature of the water.

In 1845, Poiseuille[4] experimented with the flow of water through capillary tubes. He deduced the following law for stream-line flow, known as Poiseuille's law, which has since been derived theoretically:

$$F_l = \frac{64\, \mu\, L\, V}{2\, g\, D^2} \quad \text{.......................} (1)$$

in which, F_l = loss of force, or pressure; μ = absolute viscosity; L = length of experimental pipe, in feet; V = average velocity, in feet per second; g = acceleration due to gravity; and D = mean diameter of pipe, in feet. Equation (1) may be expressed in terms of the Reynolds number and the Darcy friction factor, as follows:

$$f = \frac{64}{\mathsf{R}} \quad \text{.......................} (2)$$

in which, f = Darcy's friction factor; and R = Reynolds number.

In 1857, Darcy[5] conducted a series of experiments on the flow of water in cast-iron pipes with diameters ranging from 0.5 in. to 20 in., obtaining the formula,

$$H_f = \frac{V^2\, L}{c^2\, D} \quad \text{.......................} (3)$$

in which, H_f = loss of head due to friction; and c^2 = a coefficient which Darcy considered to be constant for each type of surface. The Darcy formula is now usually written in the form,

$$H_f = \frac{f\, L\, V^2}{2\, g\, D} \quad \text{.......................} (4)$$

[5] "Recherches expérimentales relatives au mouvement de l'eau dans les tuyaux." par H. Darcy, *Mémoires* des Savants Etrangers, Vol. 15, 1858, p. 141.

in which, $f = \frac{2\,g}{c^2}$. The friction factor, f, will be used throughout this paper as the measure of frictional resistance.

By a study of Stokes' equations of motion, Reynolds[6] conceived the idea that a criterion to determine whether flow would be stream-line or turbulent might be expressed in the form,

$$\mathsf{R} = \frac{D\,V\,\rho}{\mu} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

in which, ρ = density, in pounds per cubic foot. In 1883 he confirmed this theory experimentally by observing dye introduced into flowing water in glass tubes. The value of Reynolds number, $\frac{D\,V\,\rho}{\mu}$, at which change from one flow form to the other takes place, is modified more or less by conditions at the inlet of the pipe, by roughness, the amount of curvature, etc. A reasonable mean value to accept as the transition point between stream-line and turbulent flow is $\mathsf{R} = 2\,100$.

Working with the experimental data of Saph and Schoder[7] on flow of water in smooth brass pipe, Blasius[8] obtained the empirical formula,

$$f = 0.316\ \mathsf{R}^{-0.25} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Reynolds numbers for these experiments were less than 100 000. Later experiments on smooth pipe show that the Blasius formula does not fit the data for Reynolds numbers greater than 100 000. Nikuradse[9] obtained the relation,

$$f = 0.0032 + 0.221\ \mathsf{R}^{-0.237} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

from his experiments on smooth pipe, with R as high as 3 200 000. Drew, Koo, and McAdams[10] obtained the formula,

$$f = 0.0056 + 0.500\ \mathsf{R}^{-0.32} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

from a study of all available experimental data on smooth pipes.

Experiments with Artificially Roughened Pipes.—During the fifteen years since about 1920, Schiller, Hopf, Fromm, and Nikuradse have experimented with artificially roughened pipes to determine whether roughness follows the law of similitude. In order to have similitude, corresponding surface measurements or dimensions of roughness elements in pipes must be in the same ratio as the radii, such that, if k is the measure of absolute roughness and r is the radius of the pipe, the ratio, $\frac{k}{r}$, is a constant. Factor k, expressed in inches, is a complete measure of the size, shape, and distribution of the individual roughness elements. As there is at present no method for measuring or defining roughness, the symbol, k, is hypothetical.

[10] "The Friction Factor for Clean Round Pipes," by Drew, Koo, and McAdams, *Journal*, Am. Inst. of Chemical Engrs., Vol. 28, p. 56, 1932.

Schiller[11] experimented with artificially roughened pipe of three sizes: 8 mm, 16 mm, and 21 mm, in inside diameter (1 in. = 25.3998 mm). The roughness consisted of spiral threads cut into the inner surfaces. Two arrangements of threads were utilized. In one, the pitch was 0.8 mm, and the depth, 0.6 mm; and in the other, the pitch was 0.4 mm, and the depth, 0.3 mm. The results of Schiller's tests are shown in Fig. 1. (Curve (3) indicates results for the 8-mm pipe with the finer roughness, and Curve (2), the 16-mm pipe with the coarser roughness. If the experiments on the two pipes conformed to the principles of similitude, Curves (3) and (2) should coincide since the roughness elements were proportional to the radii. The discrepancy may be attributed to the short calming lengths which appear to have been inadequate, and also to the fact that the roughness in the calming section of each tube differed from that in the test portion.

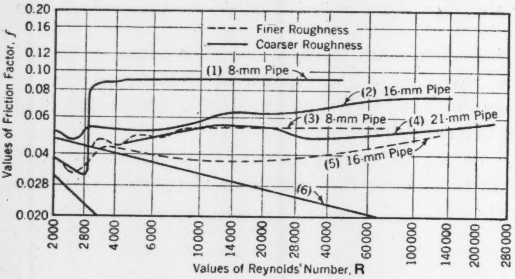

FIG. 1.—RESULTS OF EXPERIMENTS BY SCHILLER.

In investigating roughness in rectangular closed conduits, Ludwig Hopf[12] came to the conclusion that the friction factor depended upon three quantities: The cross-section of the conduit; Reynolds number; and a number which characterizes the roughness. He stated that the number for specifying the roughness appeared to require several dimensionless quantities to specify completely its size, shape, and distribution. Hopf also decided that there were two kinds of roughness, which he called "wall-waviness" and "wall-roughness." An example of the first is wood pipe or asphalted iron pipe, and an example of the second type is provided by the bare surface of cast-iron pipe.

Fromm's[13] investigations of relative roughness were carried on shortly after those of Hopf and with the same experimental equipment. In each of the roughnesses tested, several values of the hydraulic radius were used. For those cases in which f becomes constant for larger values of **R**, the effect of the change of hydraulic radius may be expressed by the formula,

$$f = (\text{constant})\ d^{-0.314} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

in which, d is the depth of section, and the constant is dependent upon the absolute roughness, k', of the surface.

Whereas Hopf, Fromm, and Schiller investigated relative roughness over a comparatively limited range of Reynolds numbers, Nikuradse[14] obtained values of f within the range of turbulent flow up to a Reynolds number of 1 000 000. He used roughnesses varying from fairly smooth surfaces to projections equal to one-fifteenth of the radius. These roughnesses were produced by glueing sand to the inside of three sizes of pipes (diameters, 2.5 cm, 5 cm, and 10 cm). The diameter of the sand grain, k', was taken as the measure of absolute roughness, k, the relative roughness being $\frac{k'}{r}$. Sand was selected of such diameter that $\frac{k'}{r}$ was the same for the three different sizes of pipes. Six different values of $\frac{k'}{r}$ were used. The results of the experiments are shown in Fig. 2. The tests show that the principle of similitude applies accurately to pipes roughened in this manner. For the range of Reynolds numbers in which f is constant, Nikuradse gives the formula,

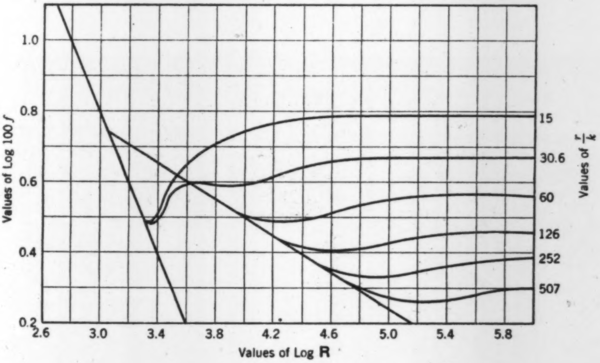

FIG. 2.—RESULTS OF EXPERIMENTS BY NIKURADSE.

$$f = \frac{1}{\left(1.74 + 2 \log_{10} \frac{r}{k'}\right)^2} \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

APPARATUS

The experiments undertaken in this investigation were conducted at the University of Michigan, Ann Arbor, Mich. The apparatus is illustrated in Figs. 3 and 4. The quantity of water used in the experiments varied from 10 to 400 gal per min. Two orifices were used for measuring, one for small, the other for large, flows. Fig. 5 shows the orifice layout. Two differential manometers were used to measure the pressure drop across the orifice. One of the gauges contained mercury and the other acetylene tetra-bromide (specific gravity, 2.97). Water filled all the spaces between the gauge liquid and the pipe.

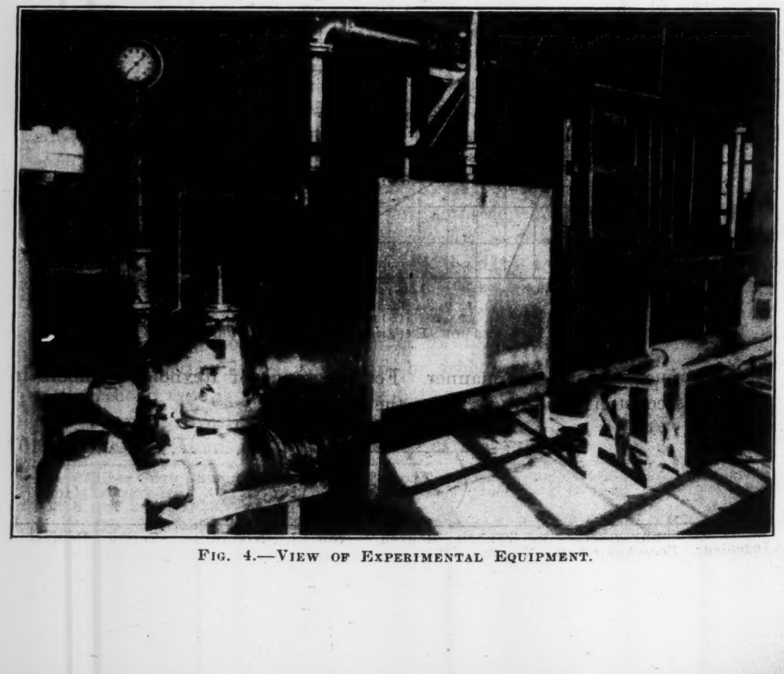

FIG. 4.—VIEW OF EXPERIMENTAL EQUIPMENT.

As the accuracy of piezometer rings is questionable in rough pipes, piezometer tubes of special design (see Fig. 6) were used to measure the pressure drop due to friction. These tubes were closed at the end, with a transverse opening $\frac{1}{4}$ in. from the end of the tube. A diagram of the test-section manometers is shown in Fig. 7. Details of connections of copper tubing to manometer glass are illustrated in Fig. 8. Manometer *A*, Fig. 7, contained mercury; Manometer *B* contained acetylene tetra-bromide; and Manometers *C* and *D* contained solutions of acetylene tetra-bromide and xylene, with specific gravities, respectively, of 1.3 and 1.05. All of them were differential manometers with water acting as one liquid.

A steam coil in the reservoir was used to heat the water to the desired temperature. A thermometer, reading to 110° C, was inserted in the valve at the down-stream end of the test section to obtain the temperature of water in the pipe (see Fig. 3). To insure isothermal flow through the test section, the pipe was insulated with felt covering.

In order to obtain a definitely known roughness on the inside surfaces of a 2-in. brass pipe, 10 ft. long, which would permit the size, shape, and distribution of the roughness to be varied, a device was designed that would cut grooves with various known dimensions and with different spacings (see Fig. 9). The pitch of the thread on the shaft was 11.5 to the inch. As the cutting tool could contain from one to four cutting elements within $\frac{1}{11.5}$ in., the distribution of the grooves could be varied.

PRELIMINARY EXPERIMENTS

The preliminary experimental work included orifice calibrations, piezometer tests, and smooth pipe tests. The orifices were calibrated over the range of flows, for temperature of 72° and 158° F. Partial calibrations were made at temperatures of 55° F and 122° F. The experimental data for temperatures of 72° and 158° are shown on the calibration curves in Fig. 10 (in which, ΔH represents the pressure drop across the orifice, in centimeters of water). Curves for 55°, 95°, and 122° were obtained from the curves for 72° and 158°, by assuming the change of discharge for a given pressure drop

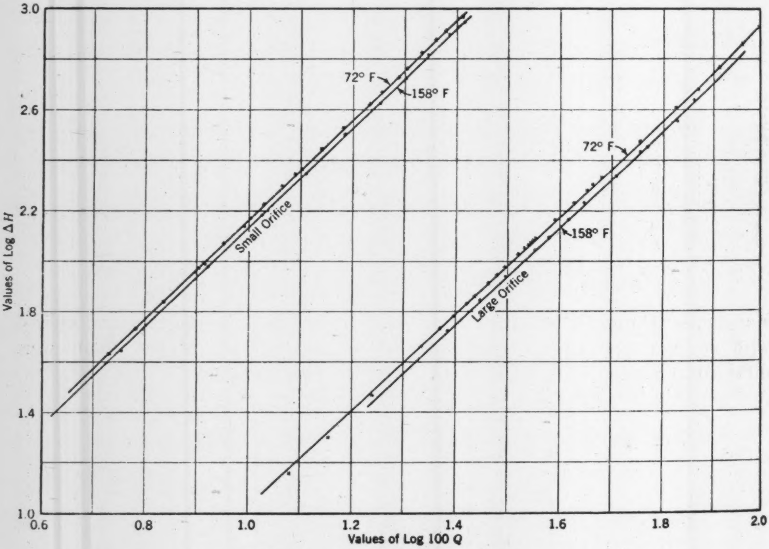

FIG. 10.—ORIFICE CALIBRATION.

across the orifice to be directly proportional to the change in viscosity of the water. A change of temperature from 55° to 158° increased the discharge by as much as 6.5% for a given pressure drop.

In order to be sure that the two piezometer tubes would give the correct difference in pressure in the test section, they were inserted into the same cross-section of a 2-in. pipe, and both were connected to a sensitive manometer. If the piezometer tubes had exactly the same characteristics and if the distribution of velocities in the cross-section were symmetrical, the manometer reading would be zero for any flow. These test readings were taken for several velocities, and they all showed the pressure drop across the

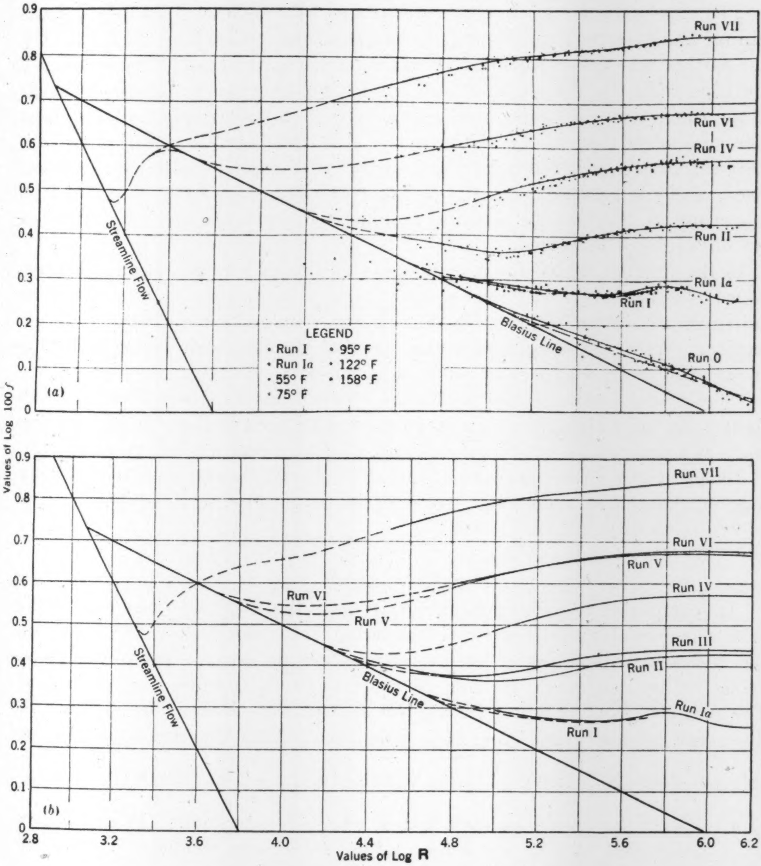

FIG. 11.—EXPERIMENTAL DATA: (*a*) FOR RUNS 0, I, I*a*, II, IV, VI, AND VII: (*b*) CURVES OF *f* PLOTTED AGAINST R OBTAINED FROM TESTS ON ROUGHENED PIPES.

manometer to be small compared with the pressure drop at the same velocity that would occur between the two ends of the test section. Accordingly, it was not necessary to add a correction to the pressure-drop measurements.

Tests were made on smooth pipes in order to obtain a basis for comparison with other investigators, and also to enable operators to become familiar with the equipment. Two sets of experiments were made with drawn brass pipe to obtain curves showing the relation of f to the Reynolds number for different temperatures (see Run 0, Fig. 11(a)). These runs were conducted in the same manner as those on rough pipe.

Experiments for Obtaining Data

The experiments on rough pipes consisted of roughening the pipes, determining the diameter, controlling the temperature, and taking readings. The test section was first roughened by running the cutter head (Fig. 9) through the pipe with the desired tool inserted in it. In order to obtain a sample of the roughness, the cutter head was run through a short piece of 2-in. brass pipe similar to that of the test section. After the sample was obtained, the 10-ft calming length was roughened in the same manner as the test section. Even with the greatest care, it was not possible to keep brass particles from collecting on the tool, so that the roughness became gradually less sharp as the cutter head advanced.

As the friction factor for a pipe varies as the fifth power of the diameter, it was important to determine the diameter accurately. This was done indirectly by determining the weight of water necessary to fill the 10-ft test section. With the weight of water, length of pipe, and density of water known, the mean diameter could be determined accurately.

The series of experiments performed on each test section was divided into eight runs, of which four were conducted with each orifice. Each run was made at a practically constant temperature. Runs were made with each orifice at temperatures of 55°, 95°, 122°, and 158° F. Each run consisted of readings of the orifice manometer, test-section manometer, and temperature for twelve to twenty different velocities.

Computations

In computing the friction factor, f, and the Reynolds number, R, the orifice manometer readings were converted into centimeters of water, and the test-section manometer readings into feet of water. From the proper orifice calibration curve the flow of water was read in cubic feet per second. The mean velocity of water in the test section was obtained by dividing the discharge by the mean area, in square feet. With this velocity (see first column, Table 2, Appendix II) the velocity head, $\frac{V^2}{2g}$, was obtained. Since $\frac{L}{D}$ is a constant for each roughness tested, when H_f (Appendix II) and V have been determined, the corresponding value of f can be computed from Equation (4) for each set of observations. The fraction, $\frac{\rho}{\mu}$, contained in the

Reynolds number is a function of the temperature, and, therefore, values of T can be traced through corresponding values in the third column of Table 2 (Appendix II), A table of values of $\frac{\rho}{\mu}$, in seconds per feet^2, was made up[14a] for each 0.1° C from 10 to 75 degrees. With V in feet per second, D, in feet, and $\frac{\rho}{\mu}$, in seconds per feet^2, the Reynolds number is seen to be dimensionless, and in consistent units. Finally, values of **R** and f, can be computed from the values listed in the fourth and fifth columns of Table 2 (see Appendix II).

Discussion of Results

Seven artificial roughnesses were investigated, three of which were cut into one set (the test section and the calming length, Fig. 3) of brass pipes and the remaining four into another set. A roughness typified by very fine grooves was first used in each set of pipes and this was followed by roughnesses with successively coarser grooves. In each case an effort was made to choose roughness designs that would conform as closely as practicable to the design that was to be used next. In spite of every precaution, however, each roughness made the one that followed more irregular than it would have been if cut directly into smooth pipe.

Relation of Friction Factor to Reynolds Number.—The experimental values of log (100 f) and log **R** for Runs 0, I, I*a*, II, IV, VI, and VII, are plotted in Fig. 11(*a*). As Run III had approximately the same friction factors as Run II, and Run V approximately the same as Run VI, their results are not given. The curves obtained from plotting log (100 f) against log **R** for all the runs on rough pipes are shown in Fig. 11(*b*). Run 0, Fig. 11(*a*), was made on smooth pipe. The dotted line through the smooth-pipe data is a graph of Equation (7). This line is seen to be in good agreement with the data. The left-hand portions of the curves of Fig. 11(*a*) and Fig. 11(*b*) are broken to indicate that these sections were not obtained experimentally, but constructed according to Nikuradse's curves (Fig. 2).

The runs were made at different temperatures with the twofold purpose of increasing the range of Reynolds numbers and of obtaining information concerning the value of f, for rough pipes, as a function of the Reynolds number. As the ratio, $\frac{\mu\,(55°)}{\mu\,(158°)} = 2.98$, and as the density decreases very slightly with increases in temperature, changing the temperature of the water from 55° to 158° F increases the value of $\frac{\rho}{\mu}$ almost three times. With this temperature change, therefore, it was possible to obtain a variation in Reynolds numbers almost three times greater than would be possible, for the same velocities, with water at one temperature. From the standpoint of results obtained, experimenting with water at these temperatures was practically equivalent to running tests with other liquids which had corresponding values of $\frac{\rho}{\mu}$. To obtain the values indicated by any of the points on the curves shown in Fig. 11(*a*) would require velocities about three times as great if tests were run at a temperature of 55° F as would be required at a temperature of 158° F. In spite of the change in impact brought about by this velocity change, the friction factor remains the same. As comparatively few experiments have been conducted on artificially roughened pipes with viscosities other than those of water at temperatures between 32° and 75° F, these tests over a greater viscosity range furnish additional proof that, for a given rough pipe, f is a function of the Reynolds number.

[14a] The values of ρ and μ were taken from "Elements of Chemical Engineering," by Badger and McCabe.

Photo-Micrographic Study of the Roughnesses.—As a means of determining as closely as possible the shape of grooves in each test section, photo-micrographs, magnified to four times the actual size, of the pipe sample and cutting tool were taken for each roughness. In Figs. 13 and 14, photo-micrographs are magnified to 2.94 times their actual size. In some cases a groove intermediate between that of the cutting tool and the sample seemed to represent best the form of the roughness. In other cases (depending upon the number of previous cuts in the pipe, the wear on the cutting tool, and the clearness of the photo-micrographs), the roughness appeared to be better represented either by the sample or by the tool. The number used herein to designate a type of roughness, corresponds to that used in Figs. 11(*a*) and

Roughness I Roughness II Roughness III Roughness IV

Roughness V Roughness VI Roughness VII

FIG. 12.—LONGITUDINAL SECTIONS OF ROUGHENED PIPE.

11(*b*) to indicate the run in which this roughness was used. Essential dimensions are classified in Table 1 and the roughness is shown diagrammatically for each case, in Fig. 12.

Roughness I. — The photo-micrographs of the sample and the tool for Roughness I are shown in Figs. 13(*a*) and 13(*b*), respectively. This was the first cut through the first set of pipes, and, also, the finest roughness. Unfortunately, the sample photo-micrograph (Fig. 13(*a*)) does not show the profile of the roughness in such a way that measurements can be taken from it. The cutting tool (Fig. 13(*b*)), also, was badly damaged in going through the calming length, which had been slightly deformed as a result of some mishandling in transit. The arrows in Fig. 12 show the direction of flow. Run I*a* was made with the same roughness, but with the direction of flow reversed.

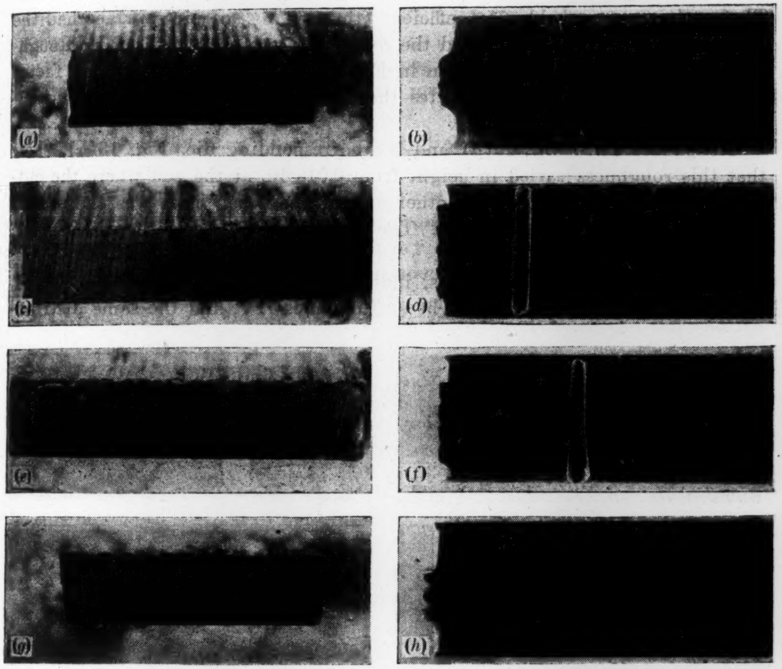

FIG. 13.—PHOTO-MICROGRAPHS OF LONGITUDINAL SECTIONS OF PIPE AND CUTTING TOOLS: *a*, *c*, *e*, AND *g*, RESPECTIVELY, DENOTE ROUGHNESSES I, II, III AND IV, WITH *b*, *d*, *f*, AND *g*, THE CORRESPONDING CUTTING DIES.

Roughness II.—The photo-micrographs for Roughness II are shown in Fig. 13(*c*) and the cutting die in Fig. 13(*d*). It was the first cut into the second set of brass pipes, and, therefore, the shape and dimensions of the roughness can be taken from the tool. The photo-micrograph of the sample does not aid much in obtaining the dimensions of the elements.

Roughness III.—The roughness indicated by Fig. 13(*e*) and the corresponding die, Fig. 13(*f*), was obtained by cutting over Roughness II with a tool designed to leave the roughness shown in Fig. 12. This was the only case of a roughness being cut to the same depth as that which preceded it. The cutting was probably 75% efficient (that is, 75% of pipe surface had the roughness shown by the tool, and the remainder was characterized by Roughness II). Roughness III as shown in Fig. 11(*b*) had a higher friction factor than Roughness II. This indicates that a projection causes greater turbulence than a groove.

Roughness IV.—Fig. 13(*g*) and the corresponding die, Fig. 13(*h*), show that this roughness varied in height from 0.018 in. at the end where the cutting began, to 0.006 in. at the other end of the pipe. This was the second roughness in the first set of pipes. The shape in Fig. 12 was a mean between tool and sample.

Roughness V.—The roughness, indicated by Fig. 14(*a*) and Fig. 14(*b*), had about the same average height as Roughness IV, and the same distribution, but was much more rough and abrupt in shape. This was the third roughness in the second set of pipes. The effect of shape is strikingly shown by the difference in friction factors of Roughnesses IV and V. In Fig. 14(*a*), the threads on the lower side are the standard for 2-in. pipes.

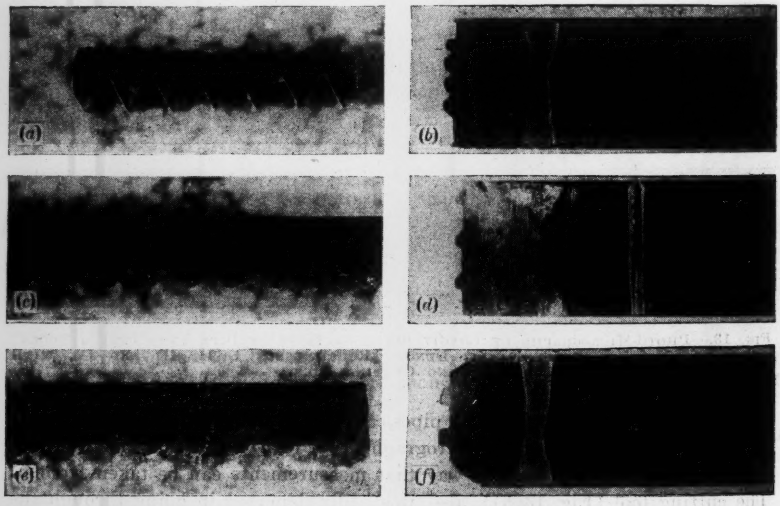

FIG. 14.—PHOTO-MICROGRAPHS OF LONGITUDINAL SECTIONS OF PIPE AND CUTTING TOOLS: THE TOP SIDE OF *a* AND THE BOTTOM SIDES OF *c* AND *e* DENOTE ROUGHNESSES V, VI, AND VII, RESPECTIVELY; *b*, *d*, AND *e*, THE CORRESPONDING CUTTING DIES.

Roughness VI.—The third and last roughness of the first set of pipes (Roughness VI) is shown in Fig. 14(*c*) and Fig. 14(*d*). The shape was wavy in character, without sharp projections, as shown in Fig. 12. This roughness had a slightly greater friction factor than Roughness V, which had smaller elements and with twice as many peaks per inch. The decidedly abrupt shape of Roughness V seems to account for its friction factor being almost as large as that of Roughness VI.

Roughness VII.—Fig. 14(*e*) and Fig. 14(*f*) show Roughness VII, the fourth cut through the second set of pipes. As would be expected with its large grooves and sharp projections, this roughness gave the greatest friction factor of any shape investigated.

Relative Roughness.—While the description of the roughnesses and their comparisons have been made on the basis of actual size, it should be remembered that this can be done only because the radius of the pipe has changed little in comparison with the changes in roughness. This investigation neither proves nor disproves the similitude theory as applied to relative roughness. Nikuradse has made a satisfactory experimental demonstration of the validity of this theory.

The friction factor is a function of the Reynolds number and the relative roughness, or,

$$f = \phi\left(\mathsf{R},\ \frac{k}{r} \right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

The relative roughness factor, $\frac{k}{r}$, must have the same value for any two pipes if they are to have the same values of f for all values of R. At present, there is no known method of determining k. It is undoubtedly some function of the size, shape, and distribution of individual roughness elements. The problem of determining numerical values of k that will define certain standard surfaces is an important one that will doubtless receive the attention of future investigators.

Comparison of Results with Those of Other Investigators.—A comparison with Nikuradse's experiments was made by investigating conditions in the region of large Reynolds numbers where the curve representing the mean of his results is approximately horizontal. Values of k' were computed from Nikuradse's formula (Equation (10)), the friction factor, f, being taken from the right side of the curves in Fig. 11(*b*). These values of k' are the diameters of sand grains required to give the same roughness effect as the corresponding grooves. Table 1 gives the value of k' obtained in this manner. In all cases, except Roughness I and Roughness I*a*, the diameters of sand grains are larger than the depths of the grooves. The shape of the rough surfaces seems to have almost as much effect as the depth of the grooves. In Runs I and I*a* the closeness of the roughness particles appears to account for the small friction factor. Run III has the same depth of groove as Run I, and the shape is not radically different; and yet the sand grains for Run III have about four times the diameter of those for Run I. Apparently, this increase in the value of f is caused entirely by the distribution of the roughness elements.

The ratio of the depth of groove to the radius of the pipe in Schiller's experiments was larger in all cases than those used in this investigation. The distributions used by Schiller were about 32 and 64 grooves per in. Because of the relatively larger grooves and the smaller range of Reynolds numbers covered by his experiments, it is difficult to establish relationships between the results of the two investigations.

Acknowledgments

The writer wishes to express his grateful appreciation to H. W. King, M. Am. Soc. C. E., and to Professor W. L. Badger, of the University of Michigan, for their interest and suggestions during this investigation; and to Mr. Weyburn M. Dodge for his aid in constructing the equipment.

Conclusion

The experiments described herein indicate that the shape of the roughness elements is quite as important as the size. This is evident from an examination of Columns (5) and (6) of Table 1, as well as Fig. 11. Runs I, II, and III, while having the same depth of groove, have a wide variation in friction factor. As the shape of Runs I and III are somewhat similar, the difference in friction factor may be attributed to the difference in distribution of the roughness elements.

APPENDIX I

Notation

The following symbols, adopted for use in this paper, conform in all essential respects with "Symbols for Hydraulics"[2] compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1929:

c = coefficient; a constant for each type of roughened surface (not to be confused with Chezy's coefficient, C).

d = depth; depth of flow; depth of section.

f = friction factor used in expressing loss of head in pipes; Darcy's friction factor; as a subscript, f denotes "friction."

g = gravity constant; acceleration due to gravity.

h = head; as a subscript, h denotes "hydraulic radius."

k = a measure of absolute roughness; k' = diameter of sand grains, taken as a measure of absolute roughness.

r = radius of pipe

A = area; cross-section area of pipe

C = Chezy's coefficient (not to be confused with c, as introduced in the paper).

D = mean interior diameter of a pipe.

F = force; total pressure; F_l = loss of pressure.

H = total head; H_f = total loss of head due to friction.

L = length of experimental pipe sections.

R = hydraulic radius (not to be confused with **R** (see Equation (5)).

R = Reynolds number; $\mathbf{R}_h$ = Reynolds number based on the hydraulic radius

T = temperature.

V = velocity; average velocity in a section.

μ = viscosity, absolute.

γ = viscosity, kinetic = $\dfrac{\mu}{\rho}$.

ρ = density

ϕ = function of.

APPENDIX II

DISCUSSION

Warren E. Wilson,[15] **Jun. Am. Soc. C. E.** (by letter).—A well-planned program of research is indicated by this paper; the author has obtained results which, without doubt, are a valuable addition to the present knowledge of the characteristics of flow in pipes. The writer will make no attempt to evaluate the results, but will endeavor only to comment on the methods used to measure the loss of head in the test section of pipe.

Differential manometers were used with the evident purpose of obtaining large readings when the loss of head was small. If one assumes that the difference in elevation of the menisci in a differential manometer gives a true measure of the actual pressure difference which it is desired to observe, and if one bases his computations on the usual formula:

$$z_m = \frac{w}{w - w_k} H \qquad \text{.......................(12)}$$

(in which z_m is the manometer reading; w, the specific gravity of water; w_k, the specific gravity of the gauge liquid; and H, the pressure difference under observation), the value of H which is calculated will generally be in error, as has been demonstrated on a previous occasion.[16]

The magnitude of the error in any manometer reading depends on the liquids and the form of the menisci. The height of rise of a liquid interface in a capillary tube may be computed from the expression,

$$h = \frac{4\,\sigma\cos\theta}{g\,D_t\,(w - w_k)} \qquad \text{.....................(13)}$$

in which σ is the surface tension expressed in dynes per centimeter; h, the height of rise, in centimeters; θ, the angle of contact between meniscus and wall of the tube; g, the gravitational constant; and D_t, the diameter of the tube, in centimeters.

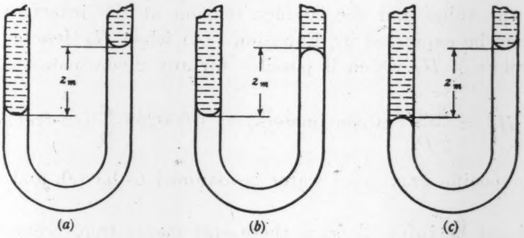

FIG. 15.

If the menisci form as in Fig. 15(*a*) the error of the reading is zero, providing the angle of contact is the same in the two tubes. If the formation is as shown in Fig. 15(*b*) the reading, z_m, is smaller than Equation (12) would indicate by an amount not greater than 2 h, in which h is given by Equation (13), since each meniscus has an effect which probably does not exceed that of a single meniscus in a capillary tube. If the formation is as shown in Fig. 15(c), the reading, z_m, is larger than Equation (13) would indicate by an amount not greater than 2 h.

---

[15] Madison, N. J.

[16] "Differential Manometers Investigated," *Civil Engineering*, January, 1934, p. 30.

As a specific case, consider the manometers used and described by Mr. Streeter. The inside diameter of the tubes was about 6 mm. The liquids were acetylene tetra-bromide, and xylene, with surface tension values of approximately 36 to 38 dynes per cm. The specific gravities of the solutions were about 1.3, 1.05, and 2.97. Assuming the specific gravity of water to be unity (that is, neglecting the effect of temperature), the values of h may be computed by means of Equation (13).

The foregoing comments have shown that the error in a reading could vary from zero to 2 h. This error will correspond to an error in the computed head, H, which is H_f and will depend on the multiplication factor of the manometer. Table 3 which is based on an assumption of the value of σ as 37 dynes per cm, and of the value of θ as zero, indicates the possible limitations of the manometer.

TABLE 3.—POSSIBLE ERROR IN H_f WHEN COMPUTED FROM z_m BY EQUATION (13)

Specific gravity (1)	Multiplication factor (2)	Height of rise, h, in centimeters (3)	Possible error in z_m, in centimeters (4)	POSSIBLE ERROR IN H_f WHEN COMPUTED FROM z_m, IN EQUATION (13)	
				In centimeters (5)	In feet (6)
1.05	20.0	5.03	10.06	0.503	0.0165
1.30	3.33	0.838	1.68	0.503	0.0165
2.97	0.508	0.128	0.256	0.503	0.0165

It is obvious that the possible error in the measurement of the loss in head does not depend on the multiplication factor of the gauge, but on the diameter of the tubes and the surface tension at the interfaces. The possible error may be expressed by Equation (14) when H_e denotes the error in the measurement of H_f which is possible for any given manometer:

$$H_e = \frac{8\,\sigma}{g\,D_t}\text{ (in centimeters)} = 0.000268\,\frac{\sigma}{D_t}\text{ (in feet)}\,\ldots\ldots\ldots(14)$$

in which the specific gravity of water is assumed to be 1.0, and θ is assumed to be zero.

It should not be inferred from these statements that Equation (14) will give an exact value for a correction to be applied to the computed loss of head. There are too many important factors which have been neglected to permit such a simple method of correction. For instance, the cleanliness of the tubes controls the magnitude of θ to a great extent. In practice, it is found that the form of the meniscus varies widely and hence the angle is by no means constant.

The writer wishes to emphasize the magnitude of the error that may occur in any one reading of a differential manometer. It is his belief that the water-air manometer is best suited to the type of work described by the author, and will give quite as satisfactory results as a differential manometer using any liquid known to him. It must not be concluded that any serious errors exist in the research reported in this paper. It seems very probable that the wide scattering of the points in Fig. 11 for low values of the Reynolds number, may be at least partly explained by attributing an error to the manometers. For the lowest head observed, 0.0265 ft in Run I, the possible error is 62%, but for all heads of 1.65 ft, or more, the error is less than 1 per cent. However, the writer has found that the variation of the readings from the value predicted by Equation (12) seldom reaches the value given in Equation (14) and probably averages about one-third this value. However, it seems reasonable to believe that, with the ordinary water-air manometer, one can obtain an accuracy of 0.003 ft of water, which is better than what might be expected with the author's manometers even when the values given by Equation (14) are reduced by two-thirds.

Richard G. Folsom,[17] **Esq.** (by letter).—Valuable experimental data regarding characteristics of rough surfaces are recorded in this paper. The method of expressing roughness in terms of the equivalent sand size is an interesting and practical one, particularly as Nikuradse[14] has obtained excellent results in the application of Equation (10). A further understanding of the frictional resistance requires a study of the mechanism of flow past the roughened surface.

In 1931, the writer conducted a series of tests[18] to investigate the characteristics of ultra-rough surfaces formed on the concentric core of an annular section. Flow pictures of aluminum-bronze particles and friction-factor determinations were made. Three views for different degrees of roughness are presented in Fig. 16 which demonstrates clearly the totally different types of flow existing for various groove dimensions.

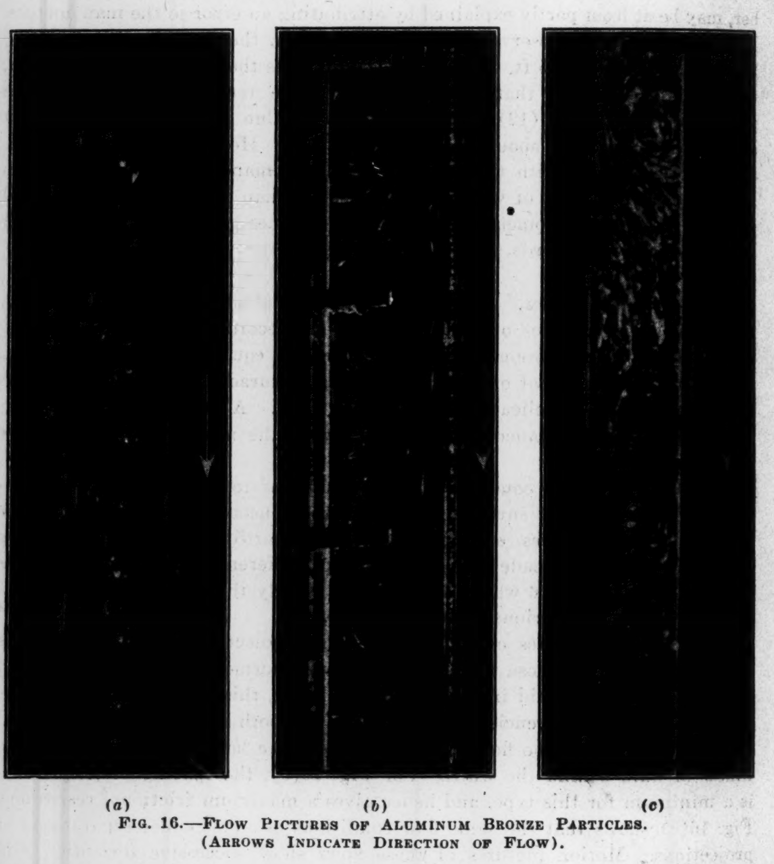
Fig. 16(*a*) illustrates conditions when the projections causing roughness are placed relatively close together. A whirl is formed in the grooves which prevents the flow of fluid into these spaces; hence, this type of roughness produces only small divergencies from flow over a smooth surface. Fig. 16(*b*) and Fig. 16(*c*) illustrate the flow when the grooves are large enough to allow the inflow of fluid behind the whirl. For Fig. 16(*b*), the spacing of projections is a minimum for this type, and hence gives a maximum frictional resistance. Fig. 16(*c*) shows that the same flow conditions occur at wider separations of projections. Motion pictures of these flows show successive formation and sweeping out of the whirls or vortices. Measurements indicated that maximum friction occurred when the depth of the groove was about one-fourth the spacing, this relation holding throughout the investigated range of relative roughnesses (ratio of projection length to length between walls).

---

[17] Instr. in Mech. Eng., Univ. of California, Berkeley, Calif.

[18] "An Experimental Investigation of the Phenomena Produced by the Highly Turbulent Flow of Water Past a Series of Sharp Obstacles," by R. G. Folsom, presented to California Inst. of Technology in 1932, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

These and other photographs indicate that a rough surface produces disturbances which spread throughout a large part of the flowing fluid. Contrary to the author's statement (under heading "Discussion of Results: Roughness III") that, "this indicates that a projection causes greater turbulence than a groove," the disturbance depends on the shape of the groove due to its control of the action of the vortices. The whirl or vortex formed has a diameter of the same order of magnitude as the depth of the groove, but the size and shape of the groove determines when the vortex will pass out into the main flow and dissipate its energy. As the roughness becomes greater, the disturbances increase with a resulting increase in energy dissipation, the latter being measured as a larger frictional drag.



(a) (b) (c)

FIG. 16.—FLOW PICTURES OF ALUMINUM BRONZE PARTICLES. (ARROWS INDICATE DIRECTION OF FLOW).

Experiments at the University of California with unsymmetrical projections in an ultra-rough surface indicate that in some cases the frictional drag is very different, depending upon the direction of flow. Thus, the characteristics shown in Runs I and I*a* as being almost independent of the direction of flow cannot be considered as general.

Table 4 contains the author's results in comparison with those given in a British report[19] for wavy or corrugated surfaces. Houghton's experiments were conducted in a 3-ft square wind tunnel with air as the fluid. The value of *f* in Table 4 corresponds approximately to Reynolds' number of 10^6. The relative roughness is the ratio of groove depth to pipe radius, or equivalent dimension. Even if the corrugation shapes and relative roughnesses differ, the author's friction factors appear to be high. In some measure at least, this result is caused by the spiral motion of the water, which is the result of the method of making the artificial roughness.

TABLE 4.—COMPARISON OF RESULTS

Experimenter	Wave length, in inches	Ratio of groove depth to wave length	Relative roughness	log 100 *f*
Streeter, IV	0.043	0.276	0.011	0.58
Streeter, VI	0.087	0.184	0.015	0.68
Houghton	3.0	0.4	0.067	0.60
Houghton	1.0	0.4	0.022	0.48

Although the author presents an excellent brief account of principal investigators in the field, the writer believes the work of Fage[20] should have been noted. This material includes pressure and friction measurements for a surface composed of pyramids. The ultra-microscopic method is used to study velocity distributions and turbulence. The magnitude of the fluctuating velocities was about 2.5 times those for smooth pipes. The data show an approximate check with von Kármán's generalized velocity representations although the disturbances due to the wall extend further into the flowing fluid with the rough surface.

RALPH W. POWELL,[21] M. AM. SOC. C. E. (by letter).—Not only is this paper based on an extensive series of experiments, clearly and completely reported, but it is an excellent summary of past work in the same field. Perhaps the most noticeable omissions in the author's references are to the work of Stanton and Pannell[22] and to the extensive collection of data published by Kemler.[23]

[23] "A Study of the Data on the Flow of Fluids in Pipes," by Emory Kemler *Transactions*, A. S. M. E., Vol. 55, HYD, pp. 7–32 (August 31, 1933).

In an unpublished study made in 1914[24] the writer offered some suggestions for future experimenters, among which was the following:

> "The most fruitful field for experiment seems then to be on rough pipes from ¼ in. to 6 in. in diameter. It has been suggested[25] that threading pipes on the inside throughout their length would give a very rough pipe whose roughness could be duplicated at different diameters. The suggestion seems good, although it opens the question, not considered in this thesis, as to what size threads on a ¼-in. pipe would correspond to a given size thread on a 6-in. pipe."

As this study applies directly to the subject of this paper, and as the results confirm many of the author's statements, it is, perhaps, not out of place to offer a brief summary.

The thesis consisted of a study, on the basis of Reynolds' number, of the previously published data on pipe flow that recorded the temperature. The principal part of the data was that published by Saph and Schoder,[7] which it was afterward found had already been studied from the same standpoint by Blasius.[8]

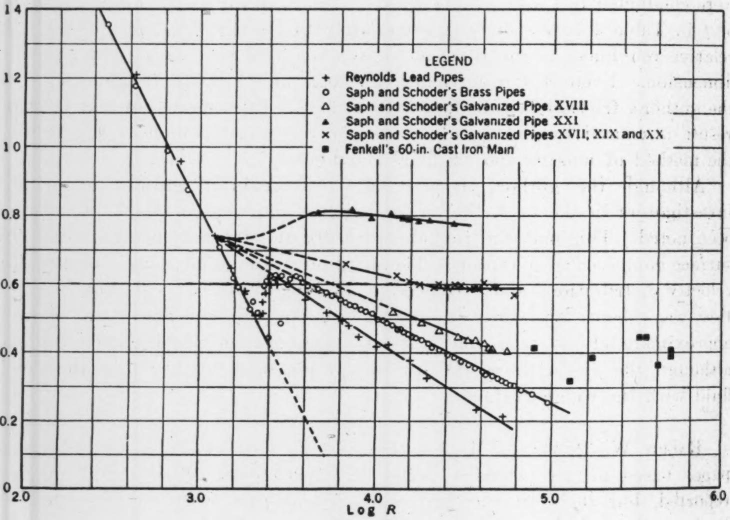

FIG. 17.

The results of the entire study are condensed into Fig. 17, which gives a plotting of f against R and corresponds to the author's Figs. 2 and 11. The points for the brass pipes studied by Saph and Schoder, represent 831 separate observations on 15 pipes ranging from 1.5 in. to 0.1 in. in diameter and at temperatures from 35.5° F to 84.0° F. These observations were re-arranged in the order of the Reynolds' numbers irrespective of what pipe they were taken on, and averaged in consecutive groups. (The only exception was in the critical region where cases in which stream-line flow seemed to be persisting were kept separate from those in which the flow was clearly turbulent.) Each point up to $\mathsf{R} = 2\,500$ represents the average of four or five determinations, generally on two or three pipes. For higher values the number in the group increased to six and then to ten; and between $\mathsf{R} = 4\,000$ and $\mathsf{R} = 40\,000$, it is twenty. One of these groups of twenty taken at random was found to include runs on eight different pipes, ranging in diameter from 1.25 in. to 0.10 in. The largest departure of any of these twenty values from the line that best represented all the runs was 3.6 per cent. The equation of this line was found to be:

---

[24] "The Flow of Water in Straight Pipes," by Ralph W. Powell, presented to Cornell Univ. in 1914 in partial fulfillment of the requirements for the degree of Civil Engineer.

[25] *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 890.

$$f = 0.329\ R^{-0.253} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

which agrees very well with Equation (6). As noted by the author, Saph and Schoder did not extend their tests to a value of **R** quite high enough to show the upward curve in the line, which was discovered later by Stanton and Pannell and confirmed by Nikuradse and others.

The plotting of Reynolds' original experiments on two lead pipes ($\frac{1}{4}$ in. and $\frac{1}{2}$ in. in diameter) was made in the same way, except that each point represents the average of only four runs. These experiments are interesting for two reasons: (*a*) They show that, compared with lead pipe even "smooth" brass pipe must be considered as having a definite roughness; and (*b*) they show noticeably larger discrepancies from a smooth line above the critical velocity and from Poiseuille's formula below it, than the experiments of Saph and Schoder. In this connection the writer stated,[24] in 1914, that "it is worthy of note that Saph and Schoder's experiments prove Reynolds' formula better than those he himself performed and used to derive it." This is all the more noteworthy because Saph and Schoder seem to have taken little "stock" in Reynolds' work, and their results had been in print for a number of years before the agreement was ever investigated.

The five galvanized pipes studied by Saph and Schoder seem to fall into three definite groups as far as roughness is concerned. Pipe XVIII (diameter, 0.85 in.) was not so much rougher than the brass pipes and each point in Fig. 17 is the mean of only two runs. On the other hand, Pipe XXI (diameter, 0.35 in.) was extremely rough and each point in Fig. 17 represents the mean of three runs. The other three pipes (diameters, 1.042, 0.626, and 0.486 in., respectively) fall between the other two and differ very little among themselves. They have been grouped together, each point representing the average of four runs.

In order to check the methods for larger pipes the values for a 60-in. cast-iron main given by George H. Fenkell, M. Am. Soc. C. E.,[26] were reduced by the same method and each point in Fig. 17 represents a single run. Only the mean temperature for all the runs was given, but temperature has little effect in this case, as the curve is nearly horizontal. Perhaps it should be noted that the slope of the curve measures the influence of temperature on the friction head. Below the critical velocity where the slope is one, the resistance varies as the first power of the kinematic viscosity. Above the critical velocity where the slope is, say, one-fourth, the exponent of R in Equation (6) is −0.25, and the resistance varies as the fourth root of the kinematic viscosity; but where the curve is horizontal, f is independent of R and change of temperature has no effect on friction head.

---

[26] *Transactions*, Am. Soc. C. E., Vol. LI (1903), p. 323.

One other point may be noted: All the lines as drawn in Fig. 17 intersect at the point, $R = 1\,162$ and $f = 0.0551$ ($\log R = 3.0652$ and $\log 100\,f = 0.7408$). This agrees very well with the intersection of the Blasius line with the stream-line flow line on Fig. 11. Therefore, the lower critical velocity will always be greater than $R = 1\,162$; as the author states, it is generally about 2 100.

If it were true that all these lines were straight and radiated from a single point, the formula would be,

$$f = 0.0551 \left(\frac{1\,162}{R}\right)^{2-m} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

in which m is the exponent of the velocity in the ordinary exponential formula for friction head in pipes, and varies from about 1.67 for lead pipe to 1.80 for wrought-iron or steel pipes in good condition. In fact, this formula holds fairly well for all these pipes except Pipe XXI for the range from $R = 4\,000$ to $R = 100\,000$ (and also, of course, below the critical range where $m = 1$); but it does not hold for higher values of R, and, as the author shows, no formula can tell the entire story in the case of very rough pipes. The relationship between f and R is so complicated that only a plotting, such as Fig. 11, will suffice.

VICTOR L. STREETER,[27] JUN. AM. SOC. C. E. (by letter).—In his analytical discussion of manometers, Mr. Wilson presents a method of finding the maximum error for one reading. The scattering of experimental results (Fig. 11(a)) for values of R less than 10^5 can be attributed, unquestionably, to inaccuracies of the manometers. Results and conclusions drawn from the paper were based on friction factors for Reynolds numbers of 10^6. For values of R equal to 10^6 and greater, losses of head in all cases, using rough pipes, were greater than 17.0 ft. As stated by Mr. Wilson, the maximum error for one reading of the manometer is less than 1% for pressure differences greater than 1.65 ft of water. The manometer with a solution of specific gravity equal to 1.05 was used for only a few readings. Its action was so sluggish that it would frequently require 30 min to reach equilibrium.

Recently, the writer has been using the micro-manometers described by Nikuradse[9], which are constructed in such a way that air-water or water-mercury may be used as fluids. This arrangement provides for a large range of pressure differences and a high degree of accuracy.

Dr. Folsom's investigation clearly shows the effect of spacing of roughness elements on turbulence formation. A new work by H. Schlichting[28], based on experiments made at the Kaiser Wilhelm Institute for Fluid Research, at

---

[27] Freeman Scholar, A. S. M. E., Karlsruhe, Germany.

[28] *Ingenieur Archiv*, 1936.

Göttingen, presents a simplified method of obtaining friction factors for practically any type of reproducible roughness. The results show that the maximum friction factor is obtained with comparatively small density of roughness elements. In his paper, Schlichting also uses Equation (10) as a basis for comparing various roughnesses.

In the roughnesses utilized by the writer a pitch of 11.5 to the inch was used. In a 2-in. pipe the angle between the groove and a plane perpendicular to the axis of the pipe is 0° 48′. This slight divergence from circular grooves perpendicular to the axis of the pipe undoubtedly has some tendency to increase the friction factor. The writer is of the opinion, however, that the differences in friction factors in Table 4 result from differences in the shape of roughness elements, which appears to have as much effect as their size.

In Fig. 17, Professor Powell presents an interesting study of friction factor-Reynolds number relationships. Equation (15) agrees very well with the Blasius Equation (6). The friction factors for Reynolds lead pipes, however, are low, resulting in values as much as 25% less than for the brass pipes used by Saph and Schoder. This variation for "smooth" pipes was not confirmed by Drew, Koo, and McAdams[10], who determined that the friction factor for smooth pipes would not vary more than ± 5% from Equation (8). This conclusion was based on a study of 1 400 observations made by several investigators on various kinds and sizes of smooth pipes. Determinations of diameters 3% to 5% smaller than actually existed in the pipes would account for these differences in friction factors.

STABILIZING CONSTRUCTED MASONRY DAMS BY MEANS OF CEMENT INJECTIONS

BY D. W. COLE[1], M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. OREN REED, F. F. FERGUSSON, JOSEPH WRIGHT, CHARLES W. COMSTOCK, V. L. MINEAR, JAMES B. HAYS, AND D. W. COLE.

SYNOPSIS

The title of this paper carries the implication of many difficulties, which to a gratifying degree were surmounted in the process described.

In scope the work embraced three principal gravity dams of rubble masonry, faced with ashlar, aggregating 14 000 ft in length and ranging from 30 ft to 190 ft in height. These structures, situated in the Western Ghauts of India, about sixty miles inland from Bombay, at 2 200 ft above sea level, have been in use since about 1917 for the storage of water for hydro-electric development under the available head of 1 700 ft. In recent years the increase of seepage through and under the dams gave rise to some apprehension as to their continued stability, and the remedy of cement injections was prescribed by a committee of consulting engineers.

Accordingly, the paper describes the methods and results of the borings and the injection of 64 000 bbl of Portland cement into 380 000 lin ft of drill holes in the three dams, working under full reservoir conditions. Incidentally, observation of the process during 2½ yr seems pertinent to the currently moot questions of gravity dam design, particularly as to the uplift and sliding influences, and as to reliance upon the usual assumptions of a monolithic structure.

GENERAL CONDITIONS

These reservoirs, all within a narrow zone of 20 miles along the crest of the Ghauts, are situated near the head of drainage areas which develop streams flowing eastward across India into the Bay of Bengal. The dams are the

---

NOTE.—Published in February, 1935, *Proceedings*.

[1] Civ. Engr., Phœnix Eng. Corporation, New York, N. Y.

means of intercepting this drainage and storing the catchment from the annual rainfall of from 150 to 250 in. precipitated during the monsoon of June to October each year. The reservoirs have a carry-over capacity for equalizing any ordinary "failure of the monsoon." The water is diverted westward through tunnels and penstocks to two power stations at the foot of the escarpment where the operating head of about 1 700 ft is utilized through impulse turbines for electric generation of power supplying Bombay and vicinity.

The climate is tropical and frostless, with four months of wet weather and eight months of dry weather, each in superlative degree. The country rock is basaltic, commonly a hard, heavy, dense, blue-gray lava formation, weathering to black in the cliffs, with relatively few fissures or partings, but frequently having a top crust of porous and unsound formation. The top-soil of the district is of volcanic origin, red in color, and of clayey texture; it burns to inferior brick, occurring in irregular pockets of the hills, as alluvium along the streams, or in thin deposits over the extensively bare outcrop of the country lava.

All the dams are constructed of this native rock, quarried and shaped at the several sites. The foundation rock is of the same character, with any unsound top crust presumably removed, although it is suspected that this lacked thoroughness in some instances. In general, the bed-rock and the rock component of all the masonry may be considered good, ranging from reasonably good in the lowest dam, Walwhan, to very good in the longest, Shirawta, and exceptionally good in the highest dam, Thokerwadi.

The other elements—mortar and workmanship—were less satisfactory. The mortar, which is peculiar to Indian construction (known as "surkhi mortar"), was prepared according to custom, wherein: (*a*) The local top-soil of the best clay characteristics is moulded and burned into a crude brick: (*b*) the brick is pulverized and mixed with a due proportion of a grade of lime which is presumed to have certain hydraulic properties; (*c*) to Mixture (*b*) is added the desired proportion of sand (which in these dams consists of the pulverized rock of the sites); and (*d*) the complete mortar ingredients are then ground together, with water, for at least 20 min. The grinding (Step (*d*)) is done in a kind of pug-mill which may be a stone wheel drawn through a circular trough by bullocks, or, on large-scale operations, may be a motor-driven heavy wheel revolving in a steel trough containing the mortar mixture. In any case the resulting mortar is handled subsequently in the usual manner; it sets slowly, ultimately attaining strength and hardness about equal to good lime mortar in brick masonry. Furthermore, the surkhi mortar has, in some degree, the qualities of hydraulic cement which promote its setting and hardening under water.

The Hindu masons are adept with their crude tools at cutting and shaping the small ashlar facing stones, and the stone setting to the neat lines of the structure is also well performed; but no derricks were used for stone setting on these dams, and both the facing and the rubble in the "hearting" were mostly of "one man size," lifted or rolled into position. Therefore, it may be inferred that the stones were imperfectly bedded in the mortar, the joints incompletely filled, and the bonding was insecure. In brief, it was not a high-grade job of hydraulic masonry, although fairly well founded on excellent bed-rock.

The resulting seepage through the myriads of porous joints tended to increase, with some evidences of leaching or erosion of mortar. Hence, the problem arose of sealing the joints, fissures, and voids in a manner best calculated to solidify the structure and stop the leaks. The objectives set up were: (1) Solidification, with assurance of continued stability of the dams; and (2) the reduction of leakage to the greatest extent practicable. It was required that all work be done under full reservoir conditions, with uninterrupted operation of the two power stations (which have a total capacity of 100 000 kw).

PLAN OF OPERATION

From the beginning it was recognized that a controlling factor would be the progress of boring. Therefore, ample equipment of several types of drills was provided and a program of use was outlined for the Shirawta Dam. This structure was most urgently in need of attention and the proposed work was most extensive—probably exceeding the work on the other two dams combined.

Electric power was the first requisite and was provided from Company lines through a few miles of branch line terminating in a small sub-station at one end of the dam. A three-phase transmission on **T**-rail poles at 50 to 100-ft intervals fixed in the top of the dam and clamped to the parapet for the entire length of the dam (7 600 ft), served for the operation of the water pumps, the electrically operated drills, and other small motors.

Air compressors, of the electric-drive, stationary type, in units of about 300 cu ft free-air capacity, were installed conveniently below the dam and served for the operation of from four to eight pneumatic hammer drills and a variable number of the air-driven cementation pumps. Occasionally, air was used for cleaning, testing, and pumping water. A 5-in. water main on the up-stream parapet extended one-half the length of the dam, continuing as a 3-in. line to the far end.

The 5-in. air main was laid along the ground at the toe of the dam for a mile, continuing as a 3-in. pipe the remainder of the way, with 3-in. or 2-in. branches to the top of the dam at intervals of 200 ft or 400 ft. Nine "percussion" (pneumatic hammer) drills were used intermittently. Twelve electrically driven rotary drills, cutting with steel shot, were used for all core drilling.

All the cement pumping equipment was actuated by compressed air, and was built for high pressure, but was used for pressures less than 100 lb per sq in. Four of these horizontal pumps were double-acting with 3-in. plungers; eight others had 2-in. plungers; and all of them had steel ball valves arranged for convenient detachability to facilitate cleaning away encrusted cement at frequent intervals. The valves of all cement pumps, and of the safety valves, were 1½-in. steel balls, steel seated; and they were very satisfactory in operation, with only moderate wear and replacement, or dressing of the removable seat rings.

Electrically driven centrifugal pumps were used for the camp water supply and for maintaining a pressure of 100 lb per sq in. in the water main on the dam to serve all drilling and cementation operations. Each of the cementation pumps required two mechanical mixing tanks (diameter, 30 in.; and capacity, 10 cu ft) for the various grout mixtures, with platforms for cement handling and with storm shelters during the monsoon season. These units of from two to four cement pumps, with accessories, were installed at intervals of 600 ft along the top of dam, with air and water connections. They were supplied with cement over a narrow-gauge track (2-ft) on steel ties running the length of the dam and on the incline, with power hoist, from cement storage and repair shops below the dam.

A machine shop with the usual equipment, lathe, drill press, shaper, and other motorized tools; a blacksmith shop; drill sharpening outfit, with oil furnace and temperature control for the accurate tempering of steel; electric repair shop; carpenter shop; pipe fitters' shop; a small stone crushing plant for making fine sand; a store house for the large supply of imported fittings and special repair parts (for the upkeep of machines coming from Europe or America), all were needed and provided for making apparatus and for maintaining it in good working order.

A camp for 500—officers, mechanics, and coolies—was constructed, Indian style, of corrugated galvanized-steel sheets on teakwood pole frames. The floors were of concrete and the roofs were covered with grass for heat insulation.

The contract for this work was awarded to the Francois Cementation Company, Limited, of Doncaster, England, which firm detailed a force of twenty-one engineers and foremen to direct operations and to train the local labor. The work progressed in three daily shifts, first at Shirawta Dam, October, 1931, to May, 1933; then at Walwhan and Thokerwadi Dams, November, 1932, to April, 1934.

DRILLING OPERATIONS

Spacing of Borings.—A cross-section of Shirawta Dam (Fig. 1) shows the position of the several series of borings. It was of first importance to determine by experiment the spacing of drill holes which would best serve for the diffusion of cement grout throughout the mass of masonry. Preliminary assumptions were that the dam was so porous that its mass could be "impregnated" with the grout from borings 50 ft apart; or, at least, that a water-tight cement curtain or cut-off might be placed through such borings at 50-ft intervals lengthwise of the dam.

The first 500-ft length of dam was drilled under this assumption, the holes being bored vertically from the top of the dam 5 ft from the water face and penetrating 10 ft into bed-rock foundation. Simultaneously with this series of top holes, a series of toe holes (termed the *X* and *Y*-series) was drilled from the ground at the toe of the dam, with the same spacing interval, but staggered between the positions of the top holes. These toe holes were designed to act first as "relief" holes while injecting the opposite top holes under pressure, and, afterward, to be themselves injected if they failed to be filled under pressure from the upper holes.

The plan was attractive, but it was not fully successful, as will be discussed under "The Cementation Process." Consequently, the spacing of primary borings was made $12\frac{1}{2}$ ft, longitudinally, beginning about $5\frac{1}{2}$ ft from the water face at the top of the dam and drilling either vertically or on a 20 on 1 incline down stream to bed-rock. The drilling was then continued from 10 to 40 ft into the bed-rock, according to indications of hardness of rock, fissures, loss of drill water, and suspicions of "ground leaks" that appeared at the toe of the dam. Even with this spacing it was found impossible to inject grout, or water, or to trace the color from fluorescein dye throughout the intervening mass of masonry which would connect with all the leaks or seepage showing in the down-stream face.

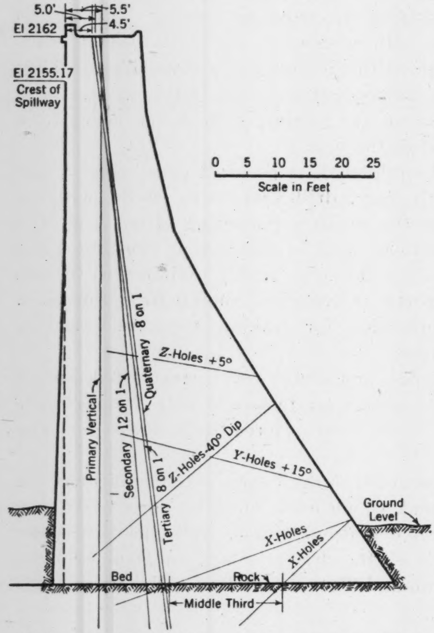

FIG. 1.—TYPICAL SECTION OF SHIRAWTA DAM SHOWING POSITION OF THE SEVERAL SERIES OF BORINGS.

Close Drilling.—As the cementation progressed it was eventually proved that close drilling was indispensable for both the top and the toe series of holes; hence, the spacing for secondary holes was made 6 ft; and, with the following tertiary, quaternary, and special intermediates, the average interval between all holes of all series became 2.1 ft lengthwise of the dam, as shown in Table 1 (Item No. 9) and Table 2. This experience applied only to the systematic location of borings throughout the length of the dam. The location of holes for intercepting and sealing the several large isolated and persistent leaks was a separate problem for each case, requiring special position, direction, depth, and methods of treatment, as hereinafter described.

This drilling experience, with the accessory cementation process, tended to confirm an original opinion that the degree of success in solidifying the dam by cement injections through borings, would be proportioned directly to the number of borings symmetrically placed within the ground plan of the structure.

Definitive Boring.—Innumerable efforts were made to intercept the path of obvious leakage by borings begun directly over the assumed path, or inclined at various angles. These borings were aimed so as to cut the path, or in any manner estimated to provide a conduit for forcing cement grout into the fissure, crack, or void that seemed to be the source of the observed leak.

Most of such efforts failed, due to the obscure relation between the outlet, the inlet, and the course of these sluggish types of seepage or small leaks. Effective boring connection with such leaks seemed to be purely fortuitous.

TABLE 1.—STATISTICS PERTAINING TO THE THREE DAMS

Item No.	Description	Shirawta Dam	Walwhan Dam	Thokerwadi Dam
1	Length of section*, in feet	....	....	800
2	Height of dam, in feet, above river bed	83	71	190

* Middle section, from Station 650 to Station 1 450.

† Long ton = 2 240 lb.

Considering that the first proposed 50-ft spacing of holes involved driving the grout through masonry interstices at least 25 ft lengthwise of the dam, when the cross-wise distance to a free outlet was much less—and that the probable shrinkage cracks would lie cross-wise rather than lengthwise of the structure—there was no logical basis for the hope of constructing a continuous curtain of cement through borings 50 ft apart lengthwise.

It will be understood that this drilling and the accessory cementation were performed for the most part while the reservoir was full, or nearly full, of water. The resulting pressure against the dam maintained the observed seepage and leaks, and tended to drift the drilling water, as well as the cement grout, toward the land face of the dam. The escape to the water face, through the shorter distance, however, interfered most with the process of cement injection.

TABLE 2.—COMPARABLE CHARACTERISTICS OF OPERATIONS ON THREE DAMS

Description	Shirawta Dam	Walwhan Dam	THOKERWADI DAM

* The long ton = 2 240 lb.

Character of Drilling.—For training the Hindu drill-runners, work was begun with the air-hammer drills on tripod mounting at the toe of the dam for the *X*-series of holes. As shown in Fig. 1 these holes were projected to intersect bed-rock at the upper and lower limits of the middle third of the base of the dam and then to penetrate the rock a minimum of 10 ft. The *Y*-holes were drilled consecutively with the *X*-holes and aimed upward to penetrate within 6 to 10 ft of the water face of the dam. A year later (spring of 1933), as the finishing touch, the *Z*-holes were drilled, from a traveling stage, at 5-ft spacing, penetrating in the directions shown, to within 6 ft of the water face (see Fig. 1).

Soon after beginning the *X*-holes the hammer-drill runners acquired sufficient skill to undertake the deep vertical holes from the top of the dam. The tripod mounting, set on a timber triangle with steel shoes, to prevent puncturing the pavement, was used most of the time, although a stanchion mounting was made in the local shop and used with good effect in speeding up the changes of drill rods. This device might easily be improved and standardized for use in lieu of the tripod in similar situations.

At first, this top drilling was done in one set-up to a finish at 10 ft in rock; then the "stand-pipe," or grouting connection of 2-in. wrought-iron pipe, 4 to 10 ft long, would be caulked and cemented in the collar of the hole, with a standard pipe coupling at the top. Later, it was found that a more secure setting of the pipe could be made by first drilling the hole only to the depth needed for the stand-pipe, then cementing the pipe firmly in place, coming back 24 hr, or more, later, and drilling through the pipe to the bottom of the hole.

With accurate bit sharpening and gauging it was frequently feasible to drill all the way from the top to the bottom of an 80-ft hole with a $1\frac{7}{8}$-in. bit through the 2-in. pipe collar.

It became general practice to drill through the 2-in. pipe to any depth less than about 130 ft, using the $1\frac{7}{8}$-in. bit with changes at 10-ft rod lengths until bed-rock was reached. Then the bit changes might be needed every few inches of depth and the gauge of the bits would be stepped down to a minimum of $1\frac{1}{2}$ in. This practice was feasible first, because of the relatively easy cutting ground of rubble masonry in surkhi mortar, and, secondly, because of the good drilling equipment and skilled management of the labor. Particular mention should be made of the special type of drill rod provided by the contractor for use with the drifter machines. These rods were of round hollow steel, upset to a diameter of $1\frac{5}{16}$ in. at the ends for connection with square threaded and shouldered nipples of the same outside diameter, which were tightened by rotation opposite the drill rotation.

The rods were supplied in even 10-ft lengths, with a sufficient number of 2-ft and 5-ft lengths, to facilitate changes in depth. Bits of cruciform pattern were found best for the local ground.

With this outfit of rods it was feasible to drill easily to depths of 150 ft with few delays and little breakage or wear of the nipple couplings, which were a controlling feature. In speed, this air-hammer drilling was from two to four times faster than core driling with shot bits in the same ground (see Table 2).

The cutting of both types of drill was faster and easier in this surkhi rubble than would be the case in well made Portland cement concrete of the same stone aggregates. Nevertheless, many of the individual rubble stones, as shown by tested cores, were as heavy, hard, and tough as the bed-rock itself. The average toughness, however, was less and the combination with the rather soft and brittle mortar made it possible for both types of drill to maintain good clearance and rapid cutting, with only occasional raveling or caving of the hole or jamming of the bit in cracks or fissures.

Core Drilling.—The core drills were excellent, heavy, electrically-driven, machines using rotary shot bits. At first, it was assumed that these drills would be used for all top-hole, deep drilling; but the hammer type of drill "walked away" from the rotary in speed of cutting so that there was a tendency to favor the use of the hammer type. This tendency was disapproved when it came to drilling the thin section of Walwhan Dam, and in all drilling of closely spaced finishing holes where the vibration of the hammer drilling was suspected of shattering the weak masonry, or of interfering with the setting, hardening, and preservation of the films of cement previously injected through adjacent borings.

The progress of the core machines was advanced first by improvements in the rod-handling derricks and in the skill acquired by the operators. Greater improvement was made by substituting smaller bits on these core machines. At first, the borings were made with $4\frac{1}{2}$-in. bits, requiring 5-in. flanged stand-pipes in the collar for grout connection.

This waste of effort and materials was corrected by use of 2¾-in. (outside diameter) bits, recovering a 2-in. core and requiring only a standard 3-in. stand-pipe with coupling. No advantage was realized from the borings of larger diameter for cementation purposes. Hollow rods in 10-ft sections, and with excellent couplings, were used. Sludge tubes were used only with the larger bits and core barrels.

To quite an extent the core machines, without derrick, were utilized for starting holes in advance for both types of drilling. The swiveling head on the core drills facilitated starting, or drilling to completion, the inclined holes which became an important feature of the work at Walwhan Dam.

In general, there was good recovery of core for determining the composition and weight of the masonry and the bed-rock. The proportions of rock to surkhi mortar proved to average about 60% rock to 40% mortar. The mortar was firm enough to permit good cores to be recovered although not in as large a proportion as in rock. Diamond drilling was not considered suitable for this ground.

Test Borings.—In the routine of work practically all borings became test holes of a sort: First, in revealing the nature of the local top crust and by indicating the length of stand-pipe needed for reaching solid ground which would not be lifted by the grouting pressure; next, by showing the depth at which partial or total loss of the drilling water would indicate a crack or fissure which must have special attention in the cementation to follow; and, on entering bed-rock, the occasional loss of water (and always the change in cutting speed, the character and color of the sludge, and the general "feel" of the ground) would confirm the height of the dam at that point and develop a profile of the foundation, of which there was no authentic record.

The *X*, *Y*, and *Z* holes served to test the outside shell of masonry and were useful in showing the degree to which the dam was saturated. With full reservoir, the structure was mostly saturated from the bottom to within 2 or 3 ft of the lake level, but at the toe the depth at which the drill would tap water sufficient to fill the boring or to maintain a spouting flow from the "stand-pipe," varied greatly. Such penetration to water from the down-stream face varied from 2 to 20 ft, but commonly it was about 12 ft; the flow seldom increased from beyond that depth, except in the vicinity of bold leaks.

Penetrating the structure from the top, the depth at which drill water would be lost varied from about 30 to 70 ft. Usually, if it occurred at all, it was about 5 ft or 10 ft above bed-rock rather than immediately at the rock contact. This latter experience, applying to all three of the dams, confirmed the judgment that, in general, the dams were well seated in water-tight contact with their foundation rock. The few exceptions to this general rule were in the vicinity of the several serious "ground leaks" appearing at the toe of the dam, as will be further described. The borings from the top were utilized for testing with compressed air, suggesting by bubbles rising in the lake the approximate position, depth, and size of the connecting joints or cracks. In the more open ground the air would show at the joints in the down-stream face.

Next to air the most searching test was a fluorescein dye solution in the water pumped into the boring under the approved grouting pressure—50 to 80 lb per sq in. This vivid green color, derived from a teaspoonful, or less, of the red powder dissolved in a pail of water, would show in face joints or in the boring pipes in from 3 min. to about an hour, and at a distance of from 10 to 100 ft away, according to the size and direction of the connecting passages.

Either or all of these tests were useful in some degree for determining: (*a*) What mixture, pressure, and quantity of cement grout would be required for a given boring; (*b*) whether wastage under water and into the lake was beyond control; (*c*) whether wastage through the down-stream joints or pipes could be stopped by caulking; or (*d*) if the use of a sand mixture might be anticipated.

FIG. 2.—VIEW OF CEMENTATION EQUIPMENT, THOKERWADI DAM; OBSERVER IS READY TO LOWER PERISCOPE INTO A BORING.

An ocular inspection was made of a few borings in Thokerwadi Dam by means of a "periscope" devised for the purpose. This consisted of two mirrors set at 45° opposite an opening in the side of a $3\frac{1}{2}$-in. galvanized tube, with a 75-watt lamp suspended between the mirrors (see Fig. 2). With this tube lowered by the light cord into the boring the illuminated side of the boring was reflected to the top by the upper mirror, giving a good picture (the obverse of the core), with a view of cracks and void spaces, down to a depth of about 40 ft for the naked eye and about 70 ft with the aid of binoculars. The device would be more valuable with better equipment and in 6-in., or larger, borings.

In the primary work the drilling got well ahead of the cementation process which, as the work progressed, tended to modify the drilling program and introduced, among other questions, the arguments for and against cementation in "stages" of depth of hole.

Valuable data pertaining to the boring operations at Shirawta Dam, from October, 1931, to May, 1933, may be summarized, as follows:

Total linear feet of percussion boring	172 578
Total linear feet of shot boring	33 951
Total linear feet, all boring	206 529
Shot Used:	
Total, in tons	20.1
Average, in pounds per linear foot of boring	1.33
Average Over-All Penetration Speed, in Feet per Hour:	
Percussion drills	5.06
Shot drills	1.67
Total Consumption of Equipment Materials, in Linear Feet:	
Drill steel	540
Percussion rods	1 700
Shot rods	280
Core barrels	430

The percussion rods used on the work were $1\frac{5}{16}$ by $\frac{7}{8}$ in. in diameter, weighing 3 lb per lin ft, with nipples. The percussion (X) bits were $1\frac{7}{16}$ in. by $\frac{3}{8}$ in. in diameter, weighing 5 lb per lin ft. The shot rods were $1\frac{3}{4}$ in. in outside diameter, weighing 6 lb per lin ft, with couplings. All threads were square, with a pitch of $\frac{1}{3}$ in. Fig. 3, depicting the borings between Sections 35 and 40 (500 ft) of Shirawta Dam, demonstrates graphically the extent of drilling required. Only the top holes are shown, the X, Y, and Z series of toe holes being omitted.

THE CEMENTATION PROCESS

The numerous questions arising in the beginning of operations were resolved successively by experiment as the work progressed. Questions as to the character of cement to be used, its strength and periods of setting, its proper mixture with water, the feasible mixtures with sand, the manner of application, the pressures for safe application under the varying conditions, the sequence of boring and grouting, the control of waste due to cement escaping out of sight under the lake level, or out of the down-stream face joints which might be, or perhaps should not be, caulked, the effective handling of the machinery, and the setting up of a system and routine which could be entrusted to the available operatives — all such questions, depending for answer on trial, observation, and discriminating judgment, came up for decision.

Incidentally, critical observation was directed to questions of foundation security, the ascertainable influences of the grouting pressures toward the uplifting effect, with its locality and extent, and to the general question of gravity dam design and some of the assumptions of that science.

Character of Cement.—Since an Indian brand of Portland cement was available, which possessed modern standard qualities, there was little thought of using anything else. There was some debate as to desirable fineness and setting time of the cement for such use, but experience demonstrated that a straight Portland grade of cement of average setting time has the requisite qualities, particularly as to hardening in place in the presence of an excess of water.

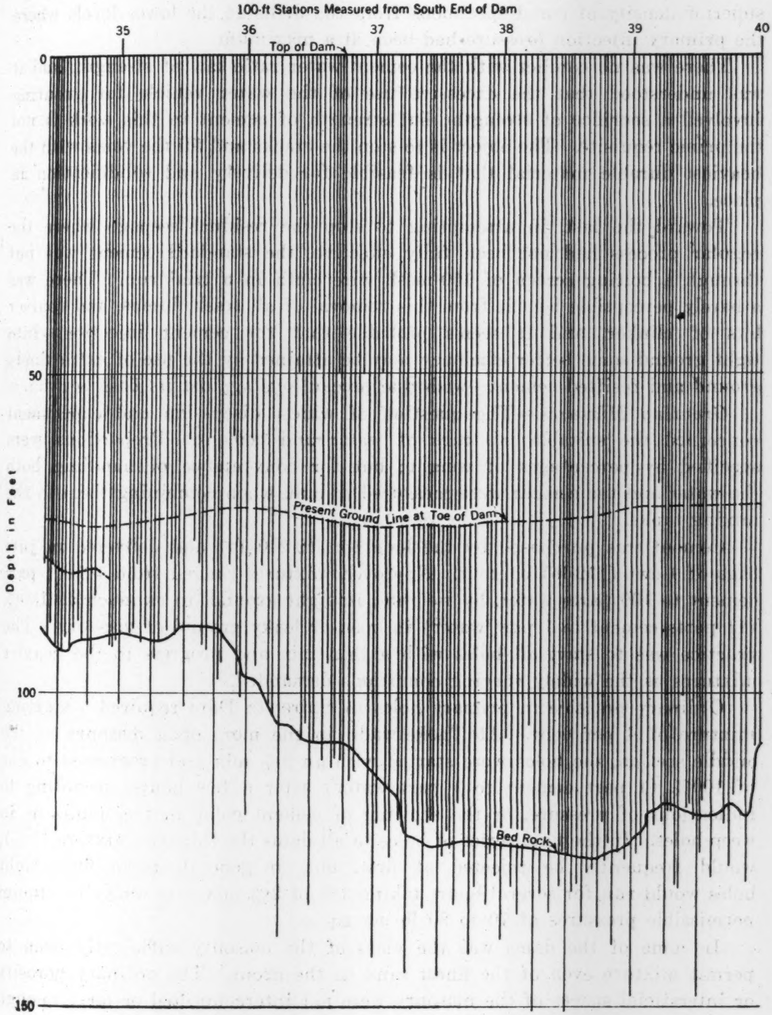

FIG. 3.—TYPICAL PART OF BORING DIAGRAM, SHIRAWTA DAM.

Throughout the job this cement never failed to set with sufficient promptness and to develop a hardness in place in the dam, under water, on the lake bottom, on the ground below the dam, from slop-over or waste through the joints, and in all crevices where it was injected. The degree of hardness and strength attained was proportional in general to the pressure of placement with accompanying extrusion of water. This was shown clearly by the superior density of cored specimens from the drills at the lower levels where the primary injection pressure had been at a maximum.

There was no conflict with the cement-water ratio law of strength, and it was understood that the excessive use of the water vehicle for grouting involved a sacrifice of strength; but strength of cement in this work is not the prime requisite. The object is to stop the cracks and fill the voids with the heaviest durable material that is feasible for delivery and solidification in place.

Toward the last, in attempting to stop the residual seepage where the regular process had not been fully effective, the standard cement was put through a bolting screen of 150-mesh wire cloth in a trial run. There was a barely perceptible benefit from this removal of all trash, lumps, and coarser bits of clinker, and it seems probable that for cement injections into tight ground some better efficiency may be attained by the use of extra finely ground and resifted cement—with due precautions against its flash setting.

Grouting Mixtures.—The question of widest discussion and experiment concerned the suitable mixtures of water and cement. Proportions were specified by percentages of weight; but for convenience of handling both the water and the cement were measured in bulk when combining them in the mixing tanks.

Cement was purchased by the long ton (2 240 lb) and delivered in jute bags of 1-cwt (112-lb) content. Approved mixtures ranged from 1% (1 part cement to 100 parts water, by weight), in tight ground, to as much as 150% (1½ parts cement to 1 part water) in open or leaky ground of masonry. The practice was to start all holes with a thin mix and progress to the heavier mixtures as the widely varying conditions demanded.

Ordinary practice in primary holes in Shirawta Dam required a starting mixture of 4 per cent. At Thokerwadi, in the more open masonry of the middle section, the holes were started with an 8% mix and progressed to one of 100% (1 part cement to 1 part water) after a few hours, according to indications of pressure, or the showing of cement color in face-joints or in weep-holes. In the final series of holes in all dams the thinnest mixture (1%), would frequently be rejected at first, but, in general, these final tight holes would run for several hours taking 1% or 2% mixtures under maximum permissible pressures of 70 to 80 lb per sq in.

In none of the dams was the mass of the masonry sufficiently open to permit mixture even of the finest sand in the grout. The ordinary porosity or intersticial spaces of the masonry were not interconnected or large enough to accept any solids coarser than the cement flour in suspension, and, frequently, even clean water dyed with fluorescein would not penetrate to a showing of color at a distance of more than a few feet from the hole under the pumping pressure.

The large use of cement at Shirawta Dam was in the numerous definite cracks, joints, leaks, and relief holes through and under the dam, and it was in this type of structure that the heavy mixtures of cement were required in combination with the prepared sand, graded through a 20-mesh sieve. The further complication of leakage and wastage of grout into the lake, through the masonry joints connecting with the holes under the injection pressure, at times made the sand mixtures imperative.

Methods of Application.—It was originally proposed to install the cement pumps in two batteries, each of six pumps at each end of Shirawta Dam, 1½ miles apart, for delivery of grout through 1½-in. or 1-in. pipes to all borings in the top and toe of the dam.

The actual beginning was made with a group of four pumps set at the cement shed near the toe of the dam 80 ft below the top, with grout delivery to the top and toe holes, through 1-in. pipes under pressure of 70 lb at the top of the dam (see Fig. 4).

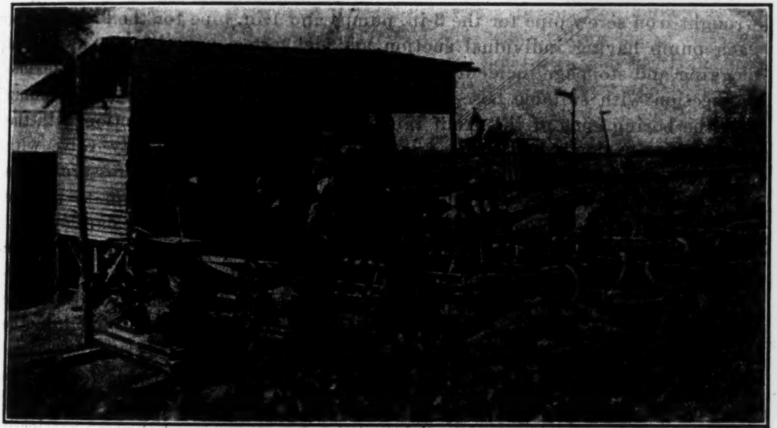

FIG. 4.—SHIRAWTA DAM; THE FIRST PUMPING PLANT, NEAR TOE OF DAM.

It was soon realized, however, that difficulties would be encountered in regulating the pressure in the borings, and that incrustation of cement in pipes and pumps was a factor that militated against distant and indirect delivery. Hence, the plan was adopted for setting the pumping plants at 600-ft intervals in tandem position against the parapet, occupying about one-half the 12-ft top width of the dam, leaving room for drilling and transport operations. This plan was applied similarly to the other dams, giving close regulation of all pressure grouting, whether in the top or in the toe borings. Portability of these cementation plants was required for the successive series of borings in the same ground, and this was readily achieved by shifting the several units of pumps, tanks, stages, and accessories on the small flat-cars used for cement transport on the narrow-gauge track—the water, air, and electric connections being ready for repeated use at each 600-ft station.

Each such plant consisted of two 3-in. plunger pumps and two 2-in. plunger pumps set at opposite ends of a double stage, 4 ft wide, 4 ft high, and 16 ft long, on which the cement in bags was stocked for mixing first through a 90-gal tank on the stage and then through a similar tank on the floor used for the pump suction chamber.

The cement stage and tanks were enclosed during the monsoon. Each tank, 30 in. in diameter, was equipped with a stirring paddle at two heights on a vertical shaft and geared to a countershaft with sprocket connections for operating the upper and lower tanks together from an electric engine under the stage. The prescribed portions of cement were measured in boxes and dumped through a coarse screen into the upper tank. The paddles being continuously rotated, served for good preliminary mixing in this tank, which was discharged into the lower tank through a screen of $\frac{1}{8}$-in. perforations made tight around the edges to prevent any lumpy or fibrous material from entering the pump suction.

The grout from the pumps was delivered to the borings through $1\frac{1}{2}$-in. wrought-iron screw pipe for the 3-in. pumps and 1-in. pipe for the 2-in. pumps, each pump having individual suction and delivery connections to avoid the clogging and stoppage incident to interconnection with other pumps. Flexible connection with suitable hose and couplings was provided both at the pump and the boring ends of the grout ranges. At each boring connection with the stand-pipe in the hole there was placed a lever type of safety valve with adjustable weight for blow-off at 70 lb, or other prescribed, pressure. This safety-valve connection was also applied at the top of the dam to the toe holes, which likewise were treated from the pumps on top of the dam.

Other fittings of the boring intake included a stop-cock on the stand-pipe above which a 4-way fitting provided the grout intake on one side. A blow-off or relief valve was placed on the opposite side, with the safety valve above or on a "tee" of the grout intake, while provision for feeding sand into the grout stream was made in the top of the 4-way cross.

A sanded mixture passing through the pumps was inadvisable for obvious reasons, so other methods were devised for introducing sand to the limited extent that was found to be beneficial. When sand was used it was practically all in connection with stopping the leakage of grout into the lake from the top holes, or wastage into ground leaks from the toe holes. In either case the sand could be run in a small continuous stream, or in handfuls, through the open-top 4-way fitting into the grout stream from the pump—falling freely into the top boring or into the down-pipe delivering to a toe boring. This process might continue for several hours until the gravity head would build up to the overflow level at the fitting, when the sand dosing would be stopped and the pump pressure applied to the neat grout stream only.

In some of the worst leaks to the lake a method was devised for delivering sanded mixtures by gravity head from two of the regular mixing tanks set on a trestle 10 ft above the top of dam. This proved quite satisfactory within short ranges of delivery pipe, but was not effective for general use (because of the clogging of the pipes and the fittings) and was abandoned in favor of the method first described. In some of the larger leaks, furthermore, there was resort to a single-drum pneumatic grouting machine, which happened to be available, but under all the local conditions this method was not as flexible, controllable, and effective as the straight pumping for the neat grout and the combination of the pumping and gravity delivery for the sanded mixtures.

Suitable Injection Pressures.—The degree of pressure safely applicable to this peculiar masonry was a matter for trial and judgment.

It was undesirable forcibly to replace any of the weak surkhi mortar with new and better cement, even had this been practicable in the section of dam as shown, with full lake static pressure against one side, atmospheric pressure on the other, and the injection pump between.

It was not desirable to apply a disrupting pressure in the process of cementation, but it was desirable to take advantage of the most effective pressure for driving the cement-laden water into the smallest passages connected with the borings and for expulsion of the excess water while compacting the cement in all accessible interstices.

With the perfectly controlled pumps, delivering through adjustable safety valves, as mentioned, it was possible (guided by the drilling log of the hole and the previously described tests) to fill the hole with the starting mixture and gradually to build up pressure to about 50 lb, at which there was little danger of any harmful effect.

In a number of early trials it was found that full air-line pressure of 100 lb per sq in. seemed to be harmless, yet, apparently, no more effective for injecting greater weight of cement. Other trials of pressure greater than 75 lb per sq in. produced some signs of distress, such as a slight upheaval of the top pavement, a slight displacement of the facing ashlar masonry, excessive leaks to the lake, or excessive discharge into relief borings. From these trials, and the general sense of caution, the limiting pressure of 70 lb per sq in. was adopted for all three dams with a few special exemptions under personal observation where 80 lb per sq in. could do no harm and might be of some help—but it was never proved that results were any better with pressures greater than 70 lb per sq in.

This regulation of pressure was applied to the normal conditions where borings could be filled with the approved starting mixture under pressure. In the very leaky ground there were many borings that could not be so filled and, therefore, required to be "coaxed" along with varying mixtures, including sand, until it became possible to staunch the waste into the lake or toward the down-stream face or the toe of the dam.

It was in this latter class of borings that the principal difficulties were encountered, particularly in the numerous cases where it was impossible for a time to tell where the grout was going or how to keep it in the wall; and, hence, a tendency was developed to persist for hours, or days on end, in pouring thin grout down a hole, siphoning through the pump and falling freely into the boring.

Sequence of Operations.—From the first it was a question whether to grout the primary holes consecutively or to skip one or more holes so as to isolate the areas under pumping pressure. Furthermore, it was a question whether to grout the top holes first with the toe holes open for "relief" (if relief were needed), or *vice versa*; and whether to grout the top (vertical) holes in separate stages of depth, from the top down, so as to "seal" the restricted horizontal zones of the dam all the way down to bed-rock before sealing the central and toe areas. It was argued by some that there was danger of inducing uplift at the heel such as to threaten the stability of the structure if the grouting was begun at the toe.

The first section of 600 ft of dam became the laboratory for testing these questions. The conclusions reached were that: (1) Isolated grouting effected no benefits; (2) toe holes appeared to be unnecessary and ineffectual for relief; and (3) the only advantage of "stage" injections was realized when the leakage from the boring was so great that the pump could no longer deliver the grout to fill the hole and build up the pressure.

Conclusion (1).—Isolated grouting proved to be of no benefit; rather, it interfered with economy, and showed some tendency to hinder the flow of grout from subsequent holes. The method of maintaining the forward side of the borings always unobstructed by previous grouting, was deemed most satisfactory.

Conclusion (2).—Toe holes seemed to be more useful for the initial grouting of bed-rock and the bed joint. This plane (the bed joint) was intersected at the third points of the base, as shown in the cross-section, Fig. 1. Incidentally, and without appearing to induce uplift at the base, or other objectionable stresses within the structure, the earlier grouting through these toe holes tended to produce a container for the upper grouting by sealing the base and the lower zone of face-joints. Caulking was indispensable in this matter, making for the retention of cement in the wall, permitting the escape of excess water in the grout, and preventing the excessive waste of cement to the ground below the dam.

Conclusion (3).—The only advantage of "stage" injections was in cases where the leakage from the boring was so excessive that the pump lacked the capacity to deliver the grout fast enough to fill the hole and build up pressure. The great disadvantage was in the delay, expense, and interference with orderly progress. Consequently, the stage system was not employed when pumping capacity was available for initial pressure on the hole. It was adopted systematically in two instances, however; First, at Walwhan Dam where the thin top section (20 ft high) had to be grouted under lower pressure than was required in the base section; and, second, at Thokerwadi Dam (190 ft high) where the upper measures were of concrete and the lower measures of loosely built rubble masonry, requiring different and separate treatment.

Conclusions (1) and (3) were confirmed by all subsequent experience on the three dams. Conclusion (2) was modified by further experience at Shirawta in places where the lower face-joints were relatively tight. It was found expedient, in such places, first, to grout the top holes and thereby in some degree to form a curtain or cut-off in the up-stream portion of the dam from top to bottom. This was the preferred method when the cement could be retained in the dam.

In localities where the leaky fissures and joints permitted excessive waste of cement through passages that could not be caulked, however, it was necessary first to seal such vents by grouting the base and lower measures of the dam through the toe holes. Consequently, the "top-toe" precedence became a question of expediency, with change of sequence to meet local conditions, in which the apprehension of uplift appeared not to be justified by any detectable symptoms.

Induced Pressures.—Observation throughout the work, with occasional testing by pressure gauges, stand-pipes, and stop-cocks, revealed a limited transference or transmission of the pump-injection pressure through the body of the masonry between adjacent holes. There was occasional, or perhaps frequent, interconnection of borings, at from 5 ft to as much as 50 ft apart, through more or less definite cracks or jointing planes. Furthermore, there were many instances in which the thin grout traveled some distance and appeared in face-joints 20 to 75 ft from the borings when under injection pressure.

In many cases with toe holes being injected, the adjacent—or, frequently, the alternate—hole would become filled with grout under nearly undiminished pressure, so that with a stop-cock on the companion hole the diffusion of grout would be completed within the area influenced by the several holes.

In the larger leaks and in the case of ground leaks, on the other hand, interconnections that occurred transferred the injection pressure, or even the low gravity pressure, through a considerable length of duct, if not over an extensive area. In general, however, there was no such spread of pressure along jointing planes from borings being injected as would result in a menace to the stability of the masonry.

Exceptions to this general rule were noted in the special situations where "ground leaks" occurred—at Stations 6.5, 17.0, 30.0, and 34.0, of Shirawta Dam. In these special cases the routine system was modified to include many additional borings and devices for throttling the gushing leaks gradually while aiming to avoid dangerous intensity and areas of applied pressure.

Routine of Cementation.—Usually, holes were drilled well in advance of the grouting so that the latter process, in a given series of borings, could be advanced in the consecutive manner, with the forward breast of the dam as free as possible for the infiltration of grout. The first move would be to wash out the one or more holes to be injected, making sure of the removal of all drill sludge or subsequent ravelings, down to the bottom of every hole, with a tolerance of 1 ft, or 2 ft, where complete clearance was difficult.

There was a tendency for these borings to accumulate sediment after standing some time, even when they had been plugged at the top after the drilling was completed. The drilling log would be studied for indications of loss, or inflow, of water, which study would be supplemented by the air, water, or dye tests as required, all having the effect of cleaning the walls of the boring and flushing out any cracks or fissures that would serve as conduits of grout into the masonry. Usually, a leakage test would be applied by measuring the rate of inflow under gravity head from the top of the dam. This rate varied from 3 to 30 gal per min, or more.

The top fittings, stop-cock, safety valve, blow-off, and the intake for sand, would then be placed, and the grout connection made. One tank of clear water would go through the pump, to expel the air, fill the boring, and, in tight ground, initiate the pressure, although in most ground of primary to tertiary borings the total delivery of the pump up to 30 gal per min would fall down the hole without producing pressure.

The addition of from 1% to 8% of cement to the water at first would sometimes initiate, say, 20 lb of pressure at the top of the dam, and this would be considered a satisfactory working pressure for half an hour, or half a day, according to the "feel" of the ground. There was always the danger of choking the hole and sacrificing the penetration of the finer connecting fissures by too much cement, too much pressure, or too much speed of delivery. Therefore, the vigilant regulation of mixture, pressure, and speed of pump was required continuously.

For safety, the rule was: "When in doubt, continue the thin mix and low pressure." Consequently, the operating foreman tended always to produce a tenuous mix and low pressure, or no pressure. The high record for this cautionary state of mind was the "injection" of one of the primary holes by pumping the 2% to 4% mix to the intake fitting and letting it fall down the hole nearly continuously for three weeks before the grout clogged and became subjected to pressure. Afterward, it was discovered that much of the cement had accumulated and set hard in a flat cone at the bottom of the lake against the dam. A somewhat less flagrant case of caution occurred on the opposite side of the dam in a boring that consumed nearly 100 tons of cement during a week of pumping in a mixture of from 2 to 100 per cent. Most of this cement was accounted for later by trenching in the rock spoils below the dam where a fairly good grade of concrete had been secretly produced by the infiltration method. (See Table 3 for estimated losses of cement.)

Much experimentation was devoted to the determination of the optimum mix, with ideal pressure and rate of delivery. The optimum was never found. The behavior of each hole was a law unto itself. Gradually, however, the judgment was developed that the extremely thin mixture, less than 2%, was not desirable or effective and that initial pressure on each hole was necessary to secure the best effect, the rate of delivery to be adjusted accordingly.

After washing and testing a hole with clear water, therefore, the approved routine was as follows: (1) A more careful measurement and adjustment of the mixture; (2) constant inspection of pumps, pipes, fittings, strainers, etc., for assurance that there was no stoppage along the line and that the indicated pressure was on the boring rather than on some plugged connection; (3) beginning with a 4% mixture, delivered fast enough to fill the boring, and to develop 10-lb pressure at the top within half an hour; (4) holding that pressure as long as any good effect appeared in the form of grout spread in the down-stream face-joints, or otherwise as might be judged; (5) thickening the mix to 8%, 16%, and as much as 100% if no waste was detected in lake soundings or in uncaulked down-stream joints or vents; (6) continuing to adjust the mixture and the pressure to the best balance for maintaining the injection during a maximum period and for a maximum weight of cement retention in the dam; and, (7) continuing the injection to "refusal" at a pressure of 70 lb per sq in.

TABLE 3.—SUMMARY OF CEMENTATION OPERATIONS

Thoroughness, rather than speed, was always the rule of action; hence, it was not the practice to force the pressure at once to the maximum, but rather to give every opportunity for the most fluid mixtures of cement to penetrate into the smallest and most remote fissures or voids which were accessible from the boring under treatment. As the work advanced through successive series of borings, the masonry became tighter, absorbed less grout per boring, and the flow became more sluggish.

Accordingly, because the pumps and pipes became encrusted with cement, the practice was developed of connecting two, three, or four adjacent borings to a single pump through its 1-in. delivery pipe, thereby speeding the main flow while retaining the desired pressure and obviating the clogging of apertures and pipes. These multiple connections could be made only with holes of similar absorption; otherwise, a loose hole in the group might take an undue proportion of grout and prevent the other holes from securing their effective pressure and share of the fluid.

Caulking Vents.—An important part of the cementation process was to caulk the face-joints of the masonry in order to retain the cement in the wall. At innumerable joints between the small-sized ashlar facing stones, in both faces of the dam, the pointing mortar had long since disappeared. On the up-stream face, in the narrow zone exposed above lake level, these joints were readily caulked against any escaping cement. Below lake level this was not expedient without the aid of a diver, and it seemed inadvisable to retain a diver for full time at the site to repair the occasional bad leaks under water. Many of the under-water leaks could be stopped by adjusting the cement mixtures and pressures or, in obstinate cases, by dosing the mixture with sand. The introduction of sawdust or rice chaff was suggested for "choking" these troublesome leaks to the lake, but this was discouraged, and only the selected sand was approved as being heavy and imperishable.

The most serious difficulty up stream was to indentify a leak at a great depth under water. The volume and time interval of rising air bubbles would show roughly the extent and position of some of the larger leaks, whereas soundings with a cutting-edge and a 2-in. pipe trap-valve, would detect deposits of cement on the lake bottom below the leak. On the down-stream face the joints were caulked systematically by a gang of about twenty men during the primary grouting, diminishing gradually toward the last, when only occasional joints required such attention.

At first, an effort was made to clear the joints of loose mortar and to insert more or less continuous strands of old rope packing; but it was soon found best to leave all joints open for the free escape of water and to resort to caulking only when the cement that escaped was of the same density, approximately, as the mixture that was being injected.

Sometimes a hole, or a group of holes, would be under pressure for hours before the cement color would show in the extruding water. At other times, the full mix would show almost immediately after starting an injection, with water and cement being expelled over large areas of face-joints opposite and at considerable distances lengthwise of the dam from the positions of the borings.

Equipped with ladders, slings, kits of tools, a supply of hemp rope strands, old bag strips, and wooden wedges, the caulking force was in constant readiness to staunch the waste of cement as soon as the inspector would decide that sufficient water had escaped and it was desirable to hold all cement in the wall and force the water and grout to further penetration. In primary work large quantities of the old rope strand were caulked in tight or held in place against the pressure by wooden wedges driven into the joints. Toward the end (and for the most part, at Walwhan Dam), strips of old cement sacking, caulked lightly in place, were found most convenient and effective in the tighter joints having less residual pressure from the injection.

A notable phase of these caulking operations was the occasional uplifting, or displacement, of the down-stream ashlar, which was poorly bonded into the rubble masonry. In fact, the facing ashlar was a veneer rather than an integral part of the dam. In numerous cases a single ashlar block would be lifted out like a loose tooth, by the grout pressure combined with the surrounding wedging for holding the cement in the wall. In a few cases the veneer peeled until a considerable area was loosened into a "blister" and all operations ceased until the condition could be remedied. The caulking operations were an essential and successful feature of the proceedings, both at Shirawta Dam and at Walwhan Dam; at Thokerwadi Dam only a little caulking was required.

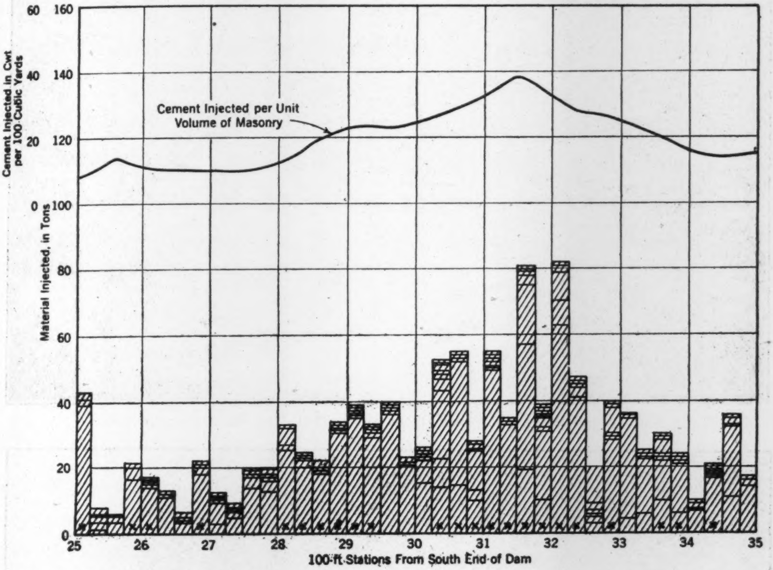

FIG. 5.—TYPICAL CURVE OF CEMENT CONSUMED AT SHIRAWTA DAM, IN EACH 25-FOOT BLOCK, LENGTHWISE OF DAM (1 CWT=112 LB).

The cement consumed at Shirawta Dam is illustrated by the typical curves in Fig. 5 (Stations 25 to 35). Sections marked x are those in which reservoir leaks, or ground leaks, caused excessive loss of cement. Figs. 6 and 7 are views of a leak at the toe of Shirawta Dam before and after cementation. Other views are shown in Figs. 8 to 12. Fig. 8 shows some typical bad leaks (including the "big leak") and small spurts before remedies were attempted. Fig. 9 demonstrates a gradual approach to the stopping of the "big leak" as it appeared in May, 1932. In Fig. 10 the ashlar masonry has been removed after a typical blow-out. No disturbance was noted in the interior masonry (see Fig. 11). In this case the pressure on the 6-in. pipes was released and borings were driven in an effort to intercept the flow along the stratum at the floor of the old inspection tunnel and below it. A view above the site of the big leak, one year after its treatment, is shown in Fig. 12. Note the 6-in. pipes.

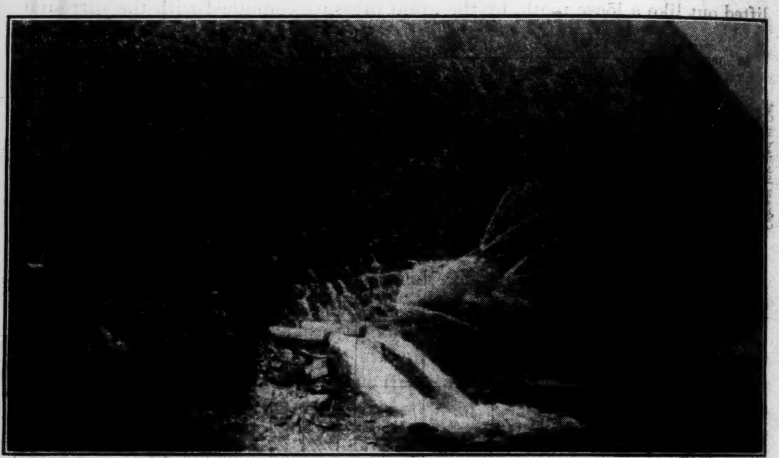

Fig. 6.—Shirawta Dam; Leaks at Toe Before Cementation.

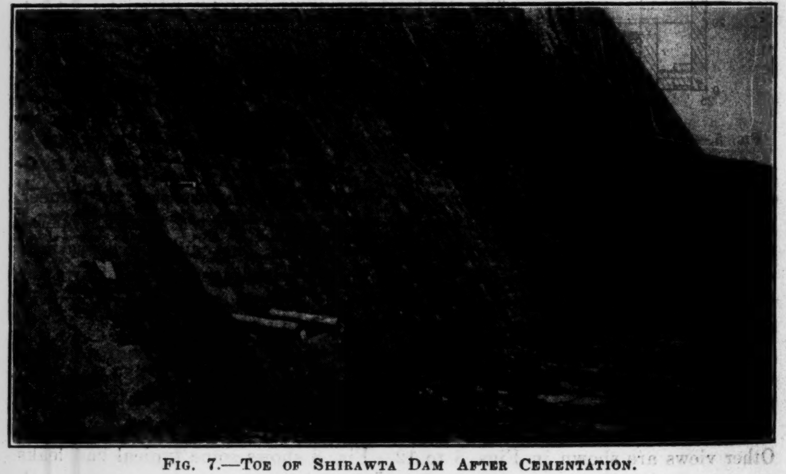

Fig. 7.—Toe of Shirawta Dam After Cementation.

Stopping the Largest Single Leak ("Big Leak")

The total leakage through Shirawta Dam was 22 cu ft per sec. Of this about 20% appeared in joints and pipes near Station 6.5 from the south end of the dam. At this point an inspection tunnel had been drifted into the dam

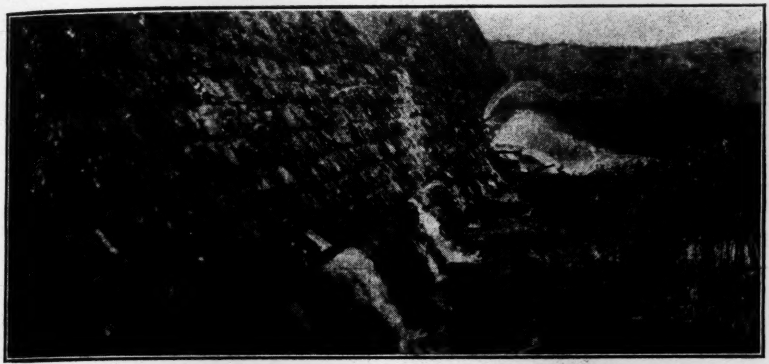

FIG. 8.—SHIRAWTA DAM LOOKING NORTH FROM STATION 6, BEFORE BEGINNING WORK.

FIG. 9.—GROUND LEAK BLOCKED BY SAND BAGS AS A GRADUAL APPROACH TO STOPPING "BIG LEAK."

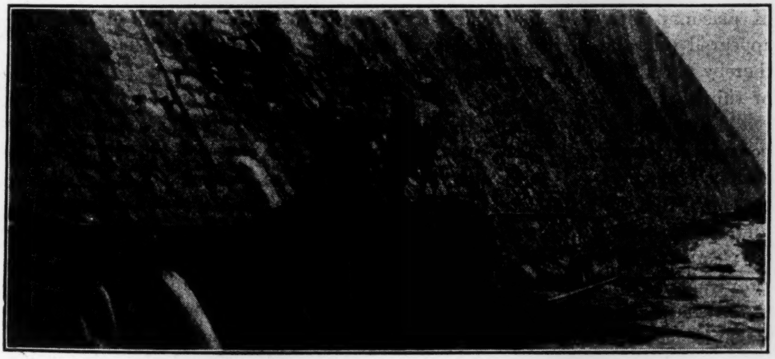

FIG. 10.—ASHLAR MASONRY REMOVED AT BLOW-OUT, SHIRAWTA DAM.

to within about 12 ft from the water-face. This tunnel had been back-filled with cement rubble and drained by two 6-in. pipes and one 4-in. pipe, perforated with 1-in. holes and bedded in the floor.

Fig. 6 shows the leakage (about 5 cu ft per sec) in the pipes and joints of this vicinity before beginning cementation. Fig. 7 shows the condition after completing the work. The final result of work on the entire dam, 1½ miles long, was the reduction of the total leakage from 22 to 2 cu ft per sec (see Tables 1, 2, and 3). The exploratory tunnel had entered a stratum of masonry 1 ft to 3 ft in height near the base of the dam in which it appeared that the mortar had been particularly inferior and seriously eroded, thereby permitting the heavy concentration of leakage at the site of this drift, or tunnel.

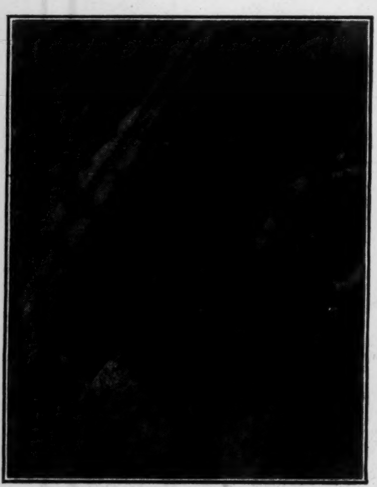

FIG. 11.—SHIRAWTA DAM, SHOWING FACING STONES REMOVED FROM BLOW-OUT LEAK (NO HARM DONE).

FIG. 12.—SHIRAWTA DAM, SHOWING Z-HOLES BEING DRILLED ABOVE SITE OF "BIG LEAK" ONE YEAR AFTER SUCCESSFUL CEMENTATION.

The cementation program throughout the length of the dam included the control and sealing of this most conspicuous leak, as well as several other serious concentrations later discovered at the base of the dam. No sealing medium other than Portland cement grout (pumped under pressure) was used, and the work was done under full reservoir conditions.

Sequence of Attack.—The first move was to proceed with the routine grouting of primary, secondary, and toe holes in the flanking sections of the dam, aiming to solidify the masonry on both sides and beneath the area of gushing leakage. In doing this there was such interconnection through the masonry, between the several borings and the 6-in. pipe drains, that much grout was wasted.

It was not considered safe to close the drains and grout the entire area under the reservoir head as magnified, or influenced indeterminately, by the pumping pressure. The policy, therefore, was to progress from one hole at a time with such adjustment of mixture and pressure as would gradually seal the face-joints, after due caulking, on both flanks of the big leak through the pipes. Narrowing the outlet in this manner resulted in troublesome loss of cement under water in the lake on that side while at the down-stream toe a bad "ground leak" was developed which rose to the surface from the base of the dam or from inaccessible joints a little above the base.

The leaks to the lake were stopped by the sand mixtures. The ground leak was first weighted with sand bags (see Fig. 9), and then intercepted by a number of drill holes suitably grouted under balanced pressure until the boils ceased and the area was solidified for retaining the subsequent injections within the dam. Further attempts to check the main gushers seemed to set up pressures in the relief borings which might become a menace to the stability of the dam, in the somewhat crippled condition of the section which at best was none too strong (see *X*-section Fig. 1).

At one stage of the proceedings a warning of trouble was given by the outburst of a leak through the down-stream face about 20 ft from the point where injection pressure was assumed to be at a maximum. This leak soon raised a blister under the ashlar veneer (afterward stripped as shown in Fig. 10), whereupon work was stopped pending a new plan of attack. During the pause in operations it was found, by air test and soundings in the lake, that leakage of grout on that side had occurred at a depth of about 70 ft, or a little above the bed of the lake. This suggested the possibility that there might be such a concentration of open jointing in that vicinity as would induce a definite intake and flow toward the drain pipes in the bed of the old drift.

100-ft Stations Measured From South End of Dam

FIG. 13.—SHIRAWTA DAM, SHOWING METHOD OF STOPPING "BIG LEAK" AT STATION 6.5.

A supply of coal ashes mixed with top-soil and a small "sweetening" of cement was assembled on the parapet and sifted down into the water against the dam directly above the suspected area of intake. A dose of the fluorescein dye was also included on the chance of tracing the color in the gushing leaks. On first trial the dye showed color within a few minutes. This was followed after a time by a trace of color in the soil, and continuing the process for some hours produced a marked reduction of flow and pressure in the 6-in. drain pipes.

This important checking of the leakage along the path of the old tunnel-drift greatly facilitated the further progress which consisted of drilling a series of six borings, 3 in. in diameter, from the down-stream toe at about 3 ft below the tunnel floor and 25 ft each side of its axis. Entering the dam at 45°, these holes converged in two sets of three holes, one in each flank, to an intersection under the tunnel containing the 6-in. pipes at a distance of 25 to 30 ft from the down-stream face of dam (see Fig. 13).

The effect of these borings was first to take away most of the remaining flow from the 6-in. pipes. Then they were grouted (with a 1:1 mix) one at a time, with controlled interconnections while using the opposite set of borings for pressure relief as needed. To make the job complete a similar group of borings was made a little higher up for sealing the entire tunnel area. These converging holes, supplementing the numerous previous holes in the regular and special series, had the effect of stopping all sub-surface leakage and solidifying the entire base of the dam up to the floor of the tunnel.

Thereafter, it became a relatively simple, and personally comfortable, matter to seal the ground above the tunnel by pressure grouting through the top holes, with a regulated vent through the 6-in. pipes. Finally, all leakage through the drain pipes and the masonry joints of that vicinity was stopped in this manner (see Fig. 7).

Other Bold Leaks.—In attempting to grout primary top holes between Station 30.0 to 34.0 (see Figs. 14 and 15), it was found impossible to hold the cement in the dam merely by caulking down-stream face-joints above the ground surface, and the usual methods failed to stop the boils rising through the back-filling at the toe of the dam. The toe of the dam, at 15 ft below the back-filled surface, was explored by digging trenches as required. A number of bad leaks were exposed, partly in the lower face-joints; the worst was a leak that rose from a bed-rock fissure 3 ft beyond the toe (see Figs. 14 and 15). Another connected series of leaks was discovered directly on the surface of the bed-rock, under the toe of the dam which, for some distance, was found to rest on the flat smooth surface of rock without any indentation or key seating. These leaks in and on the rock could not be caulked, even against the residual of static reservoir pressure. They were controlled successfully by trapping the flow in a series of 2-in. and 3-in. pipes in the bottom of the trench under concrete placed to serve also as a toe retainer for the dam in the rock-bound trench.

The pipe traps, rising to the surface, became at first the pressure relief vents for the water, and then for grout injected through top holes in the dam. By throttling these relief pipes as the grout discharge thickened and finally closing them, or extending a succession of stand-pipes until the pressure became balanced at 30 ft above ground, this section of the dam was made tight, and all toe leaks disappeared.

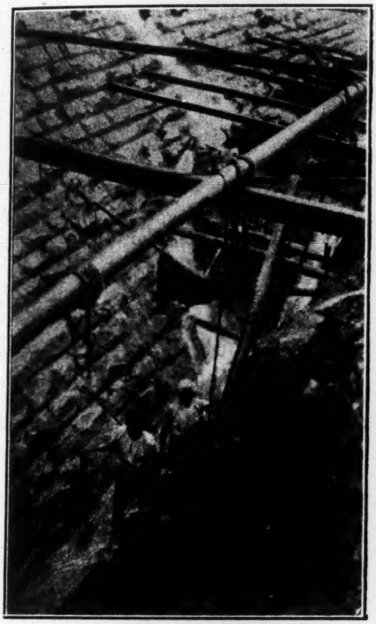

FIG. 14.—SHIRAWTA DAM SHOWING SECTION (STATIONS 30 TO 35) WHERE WORST GROUND AND TOE LEAKS OCCURRED.

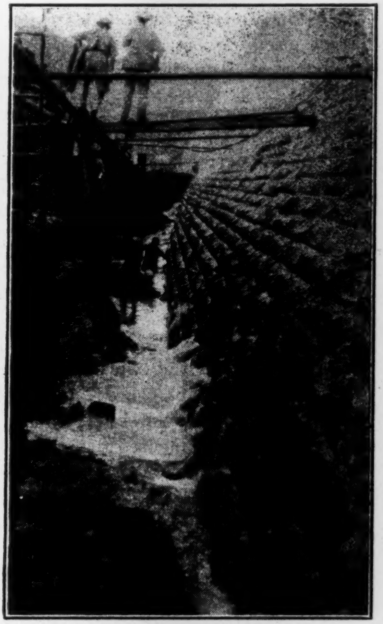

FIG. 15.—SHIRAWTA DAM; ANOTHER VIEW OF STATIONS 30 TO 35.

EXPERIMENTAL INJECTIONS

The Interior Tube Method.—Several trials were made at Shirawta and at Walwhan with a small injection pipe extending nearly to the bottom of the boring and fitted with a gland or loose stuffing-box at the top, the object being to consolidate or seal the ground from the base up. This method has succeeded in foundations where raveling ground, soft rock, or sand has required a degree of solidification in relation to other features. In the dams treated in this paper, however, the trials demonstrated that the method was less effective than the adopted standard procedure with full boring under initial pressure—variable and adjustable but continuous, from the top.

Lubrication Methods.—After the primary and secondary injections of cement grout had left something to be desired in the way of more complete sealing of residual seepage, an effort was made to induce penetration of the finer voids by the addition of some form of lubricant to the cement grout. It was suggested that compressed air might have some such effect, but when tried, produced no perceptible benefit. Calcium chloride solution mixed in the grout was no better—in fact, it made the worst record, presumably on account of its acceleration of the set. A soda-silicate, water-glass, solution appeared to help a little, but the average record of the eighty-seven borings under trial indicated that the straight 4% cement-water grout under the usual direct pumping pressure gave slightly better results than were secured with any attempted lubrication.

Chemical Treatment

Following the trials of "lubrication," as a last resort, and for the information to be derived, an attempt was made to substitute for the cement a combination of commercial salts which were reputed to have been highly beneficial in high-pressure injections for sealing wet ground in mines and shafts. In this case a section of Shirawta Dam was selected, 300 ft long, which had first been fully treated in five series of borings with the regular cement injections, and yet continued to show slight seepage over much of the down-stream face.

New borings were drilled from the top to bed-rock, at 12½-ft intervals, in this section of the dam; there were twenty-five holes in all, as exhibited in Table 1 (Items Nos. 23, 24, and 25). These borings were injected first with a soda-silicate solution immediately followed by an alumina sulfate solution. The silicate was supposed to smooth the path for the sulfate, which crystallizes and solidifies in place. Injections were made first in stages of 15-ft depth from the top down; then in 50-ft stages without any perceptible difference in effect. The maximum pressure was 80 lb per sq in. The result was a visible improvement in sealing the residual seepage, but not practically measurable in the small flows involved, which were complicated by the time interval and reservoir levels.

The conclusions regarding the chemical treatment were that:

(1) It is only applicable after thorough cementation in the usual manner for stopping all large leaks; hence, a complete re-boring of the dam is necessary, with spacing not greater than 12½ ft;

(2) The improvement in density and strength of the masonry is inappreciable;

(3) The reduction of seepage below that already accomplished by cementation is not appreciable, its durability is not proved, and the effect of the injected salts on the surkhi mortar and cement grout is a matter of doubt; and,

(4) The small immediate or visible improvement will not justify the expense.

It is probable that the reputed success of "chemical treatment" has been in rigidly confined ground where pressures of several hundred pounds per square inch were permissible for driving the fluid, with no granular solids in suspension, into the smallest passages and interstices. Manifestly, such high pumping pressure could not be permitted in a rather loosely jointed structure of relatively small dimensions resisting unbalanced static pressures, such as these dams.

The suggested limitation of benefits by the cementation process alone, opens a further field of usefulness for cement chemists and testing laboratories. A safe and reliable means of sealing the voids in otherwise completed masonry structures is needed, in order to make them virtually impermeable by water. This problem involves the production, at moderate cost, of a substance of demonstrable durability, having the property of setting or hardening in place without loss of volume or injurious reaction to any masonry constituent, and which can be carried in solution in water under pressure while maintaining a fluidity equal to, or greater than, water itself.

It may be claimed by some that the current patented or proprietary waterproofing compounds would serve for this purpose; or, it might be imagined that the old Sylvester wash of soap and alum could be injected under pressure where any solids in a water vehicle would not go; but the field is open for modern scientific experimenting.

Cementation of the Other Dams

Walwhan Dam.—The foregoing has been largely in relation to Shirawta Dam where most of the problems were first encountered. At Walwhan Dam (see Figs. 16 and 17) the same equipment and methods were used, with about the same results, as shown in Tables 1 and 2. The thin section, arched design, low specific gravity of rock and masonry, and the more general spread rather than concentration of leakage at Walwhan, introduced special difficulties requiring modification of methods.

FIG. 17.—TYPICAL SECTION, WALWHAN DAM, SHOWING ARRANGEMENT OF PLANT.

The principal difficulty was to place the borings in positions where they would be sufficiently covered by masonry to hold the grout under any effective pressure (see Fig. 18). The top 20 ft of dam had to be treated as a first stage under low injection pressure, and even then this upper stage gave insufficient support under the crown of the arches; hence, the boring was required to be done only with the shot drills, in order to avoid vibrations, and at such slopes as would pass through the piers and spandrels to reach the lower measures of the masonry where higher injection pressure was needed. Views of this work are presented in Figs. 19, 20, 21, and 22. Cement and grout are plainly visible in Figs. 20 and 21.

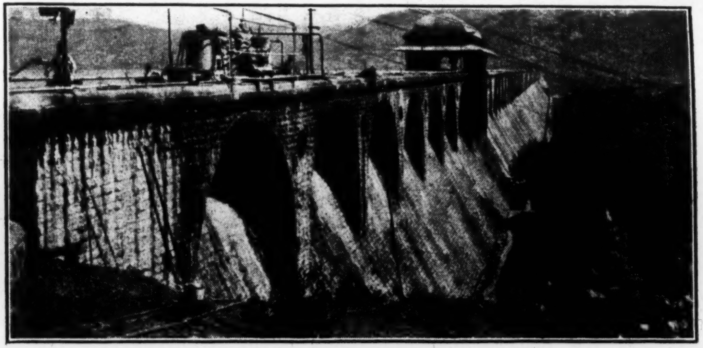

Fig. 21.—View of Cementation Pumps and Gate-House, Walwhan Dam.

Fig. 20.—Grouting Lower Z-Holes in Pairs, Walwhan Dam.

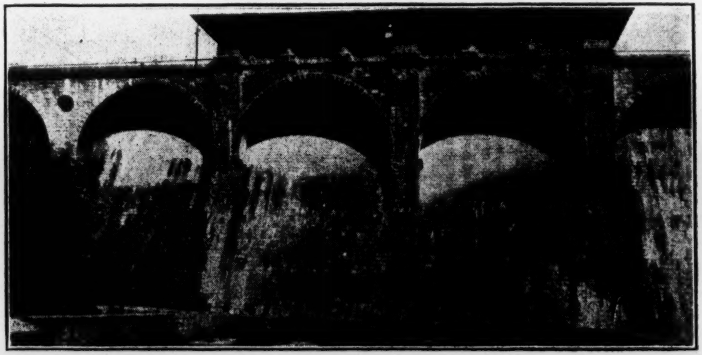

Fig. 22.—View of Gate-House and Duct Headway.

Considerable joint caulking was required in down-stream face-joints, but this was done more readily with strips of sacking and less forcible wedging than was required at Shirawta. Grout was prevented, fairly well, from escaping to the lake by the reservoir head against a thorough pointing of joints which had been done several years previous—an advantage which was lacking at Shirawta.

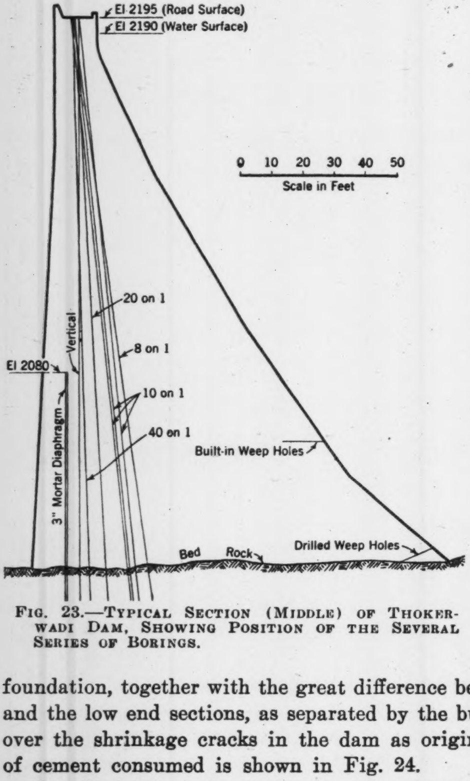

FIG. 23.—TYPICAL SECTION (MIDDLE) OF THOKERWADI DAM, SHOWING POSITION OF THE SEVERAL SERIES OF BORINGS.

The travel of grout through the wall, with interconnection of borings and venting of water and grout in the face-joints, 50 to 75 ft distant from borings under pressure, was more general than in the other dams. The progressive tightening of the masonry, with diminishing consumption of cement, in the successive series of borings and injections was equally significant; and, finally, the leakage index, 90% reduction, was substantially the same as at Shirawta.

Thokerwadi Dam. — The situation at Thokerwadi (see Fig. 23) was modified by the different design of dam, different types of masonry (all surkhi mortar, however), harder and heavier rock in the aggregates and in the foundation, together with the great difference between the high middle section and the low end sections, as separated by the buttresses which had been built over the shrinkage cracks in the dam as originally constructed. The record of cement consumed is shown in Fig. 24.

Peculiarities of the design (gravity type) included a 3-in. mortar diaphragm plastered against the hearting masonry aproximately 10 ft in from the up-stream face and only from bed-rock up to a level 115 ft below the top of the dam. The design also contemplated draining the masonry through built-in ducts emerging in 4 by 8-in. rectangular weep-holes through the downstream face. Fig. 25 shows one line of these weep-holes which carried a large part of the total leakage through the dam (4.0 cu ft per sec, which was reduced to 0.25 cu ft per sec by the cementation process). Leakage through these weep-holes was entirely stopped by the interior injections of cement (see Fig. 26).

Another large part of leakage emerged in the re-entrant angles of the buttresses where similar openings had been made for venting any water reaching the buttress through the shrinkage crack. The upper part of the dam was built of surkhi concrete with the heavy basaltic aggregates, including crushed sand. This part was first bored and grouted, with consumption of but little cement.

The plan of work was adapted to these conditions, which indicated drilling and grouting only from the top of the dam. The objective was to form an impervious curtain for extending and supplementing the "diaphragm," which had been attempted but discontinued in the original construction. The further purpose was to penetrate bed-rock and seal the bedding joint throughout the base of the dam, at the same time filling all interstices in the rubble masonry of the lower measures of the dam that could be reached by such borings in order to consolidate the structure to the utmost. (See Figs. 23 and 26.)

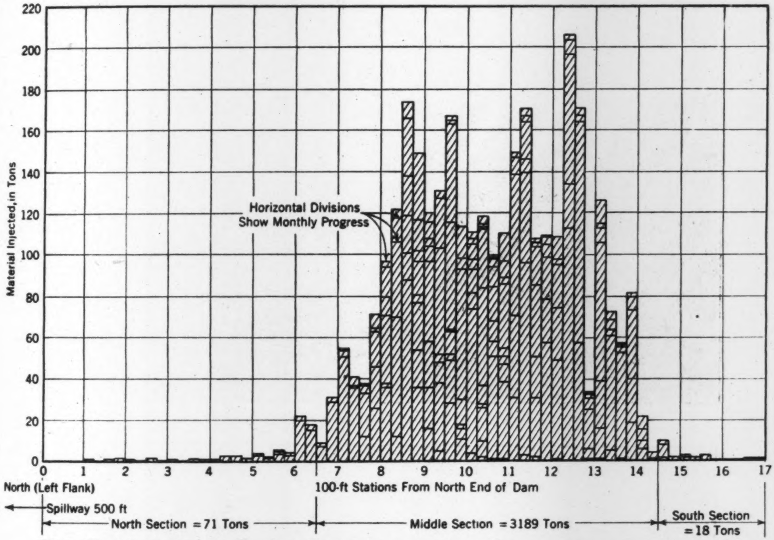

FIG. 24.—CEMENT CONSUMED, THOKERWADI DAM, IN LONG TONS (2 240 LB) PER 25-FOOT LENGTH OF DAM.

More than one-half the length of the dam (both ends) was of concrete, well seated in bed-rock, and the borings at 5-ft spacing consumed relatively little cement. The shrinkage cracks through the dam at the two buttresses, 700 ft apart, were grouted and well sealed by injection through borings intersecting each crack at 50 ft, 100 ft, and full depth. The section between the buttresses, 150 to 190 ft high, was of the same concrete in the top 100 ft; below that level the masonry was of loose, jointed rubble that raveled in the borings, permitted loss of drilling water, and required injection in several stages of depth.

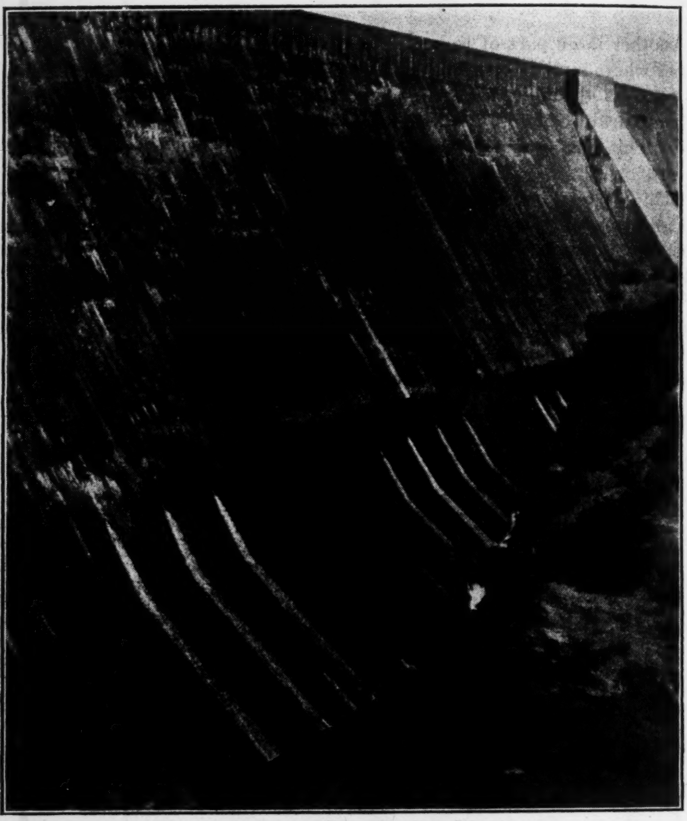

FIG. 25.—THOKERWADI DAM. BEFORE CEMENTATION.

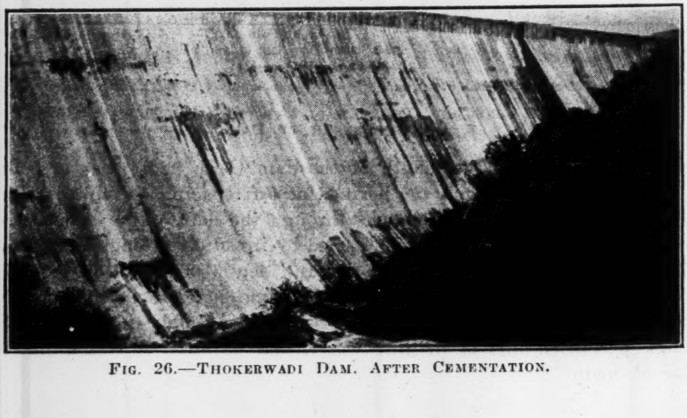

FIG. 26.—THOKERWADI DAM. AFTER CEMENTATION.

Each of the numerous borings in this section of the dam required 200 to 300 bbl of cement, in 100% mixture (1 part cement to 1 part water by weight), and the record hole took 700 bbl. No cement was lost into the lake at this dam.

There was abundant evidence that the cement became diffused widely within the masonry. For example, there was a progressive decrease in leakage of water through all the weep-holes and through the joints in the down-stream face, accompanied by a showing of cement in these vents, many of which required caulking.

No toe holes were drilled for injections from the down-stream face, as the diffusion of grout from the several series of top holes appeared to seal the bed joint and to consolidate the masonry satisfactorily. A remarkable evidence of the latter result was the progressive tightening of the drilled masonry, so that the holes ceased to ravel and cave, and the loss of drill water became infrequent. The final series of borings produced good cores of cement and refused thin grout under maximum pressure. On the whole, the results at Thokerwadi were considered rational and satisfactory, with the best showing of the three dams in $\frac{\text{cement}}{\text{masonry}}$ ratio and reduction of leakage (Tables 1, 2, and 3).

RECORD AND COSTS

A detailed record and report of all the work included a drilling log, and a report of the behavior of all borings during the injection process, in the form of a "cementation record," as shown in Fig. 27. The cost of the work is listed briefly in Table 1 (Items Nos. 27 to 34).

TOTAL											

FIG. 27.—SAMPLE SHEET FOR DAILY RECORD USED AT ALL DAMS.

These data of over-all costs cover the total expense of the work under the five items of Plant, Supplies, Materials, Labor, and Supervision. These cost figures would be applicable for estimation purposes in other parts of the world, by the use of a suitable factor of performance in drilling, under any local conditions. Knowing the cutting speed of the types of drill to be used in the local rock and masonry, either by previous experience or by a trial run, consideration of Indian labor cost would be eliminated.

The cost of plant, equipment, stores, and repairs, as shown in Table 2, should represent a maximum expense for these items elsewhere. The cost of cement in India is about the same as the average in the United States. The cost of supervision, as shown in Table 2, is a reasonable value for use anywhere to cover adequate direction and inspection of this special type of operations.

CONCLUSIONS

The main objective of this work, on all three dams, was to make the structure as solid and stable as practicable. Incidentally, the reduction of leakage, or seepage, was an object, index, and measure of success. Evidences of success in the main objective may be reviewed, as follows:

(*a*) The marked change in the character of drilling after the primary grouting, as demonstrated by increased firmness of masonry with much less raveling and choking of the borings;

(*b*) The much less frequent loss of drilling water in the secondary and subsequent series of borings as cementation progressed, until in the final series most holes were water-tight, or consumed a minimum of cement under maximum pressure;

(*c*) The greatly decreased number of cases of interconnection of borings and of leaks to the lake, or otherwise, beyond easy control;

(*d*) The recovery of numerous cores showing good penetration of cement into fissures and interstices. (The cement in these cores was found to be well hardened in place, promising durability and permanence);

(*e*) The progressive decrease in cement consumed by the successive series of borings, particularly from primary to secondary holes, shown in Table 3, until at last many holes refused grout immediately; and, finally,

(*f*) The reduction of leakage by more than 90% is good evidence of success in solidification.

The weight of evidence seems to warrant the conclusion that these dams have been stabilized and secured (largely by isolating and restricting the continuity of uplift areas), a gratifying conservation of water has been effected, and the total cost of the work was reasonable and well justified.

REFLECTION ON THE STABILITY OF GRAVITY DAMS

It will be observed that these dams of the "gravity" type, straight in plan, are of more slender profile than could be approved under orthodox analysis. (Figs. 1, 16, and 23). Probably it could be shown that there is tension in the up-stream masonry, which is certainly not of a character to withstand appreciable tensile stress.

Under the best conditions of workmanship with the given materials it could scarcely be assumed that any section of these dams would be of the monolithic character contemplated in the ordinary computations for overturning moment; and, yet, all these dams have been in successful service about fifteen years, with such deterioration from their original conditions as is evidenced by the increasing percolation during that period. Against this background, the observations incidental to the cementation process have tended to overturn, undermine, or invalidate the observer's conceptions of why a dam stands up. His net reaction is in accord with the declaration of "the necessity for abandoning the middle-third theory and the sliding factor as useful elements in masonry dam design."[3]

---

[3] "Stability of Straight Concrete Gravity Dams," by D. C. Henny, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 1041.

In view of all the phenomena presented by the cementation of these dams, however, the writer hesitates to follow Mr. Henny all the way regarding the critical question of "uplift." Rather, it might be concluded from the evidence of these thousands of borings, under their manifold pressure testing, that the occurrence, persistence, and practical effect of uplift have each been unduly magnified in the fundamental assumptions of dam design. On the other hand there would appear, from these experiences, to be good reasons for the adoption of a rational shear factor in substitution or modification of the usual sliding factor. Moreover, the common assumption of a monolithic cantilever section comes under suspicion.

While the writer was stationed for some weeks at the toe of Shirawta Dam, below a full reservoir, with the monsoon pouring water on his head and the "big leaks" sloshing water on his feet, watching the effect of pumping water and cement into the middle of the structure, he could perceive no good reason why that dam should remain stable; but it did remain stable, although sections of it 25 to 50 ft long appeared to be merely floating in water and grout. It seemed as if it had uplift enough to move it.

For the most part the bedding on rock was good and the vertical bonding of the rubble masonry was fair; but there must have been planes where uplift operated to reduce the sliding resistance. The saving factors must have been shear resistance and horizontal beam, or voussoir resistance arching between abutments of contiguous sections of the dam which had a little surplus of stability—possibly by taking the resultant thrust longitudinally.

At long last, the one conspicuous result of the cementation program was to localize, delimit, or destroy the continuity of all considerable areas of hydrostatic uplift; but, of course, this result should have been accomplished in the original construction. The lesson to be derived from this experience is, that builders of gravity dams may take some chances on their design of profiles and the governing theories of stability, but they should not take chances on the soundness of their materials or the competence of their workmanship and field direction.

Designers should "keep their feet on the ground" and beware of using values of uplift from bed-rock, based on over-inflated formulas. They should also keep their eyes critically on field practices, to the end that the essentials of durable construction shall become incorporated with approved mechanical principles.

DISCUSSION

OREN REED,[3] ASSOC. M. AM. SOC. C. E. (by letter).—A helpful service to those members of the profession who are interested in the design and maintenance of masonry dams, has been rendered by Mr. Cole. Leaky masonry dams are difficult to repair successfully.

An attempt was made to stabilize the Ringedalsvand Dam, in Western Norway, by cement injections but this method was soon abandoned for another. The writer had occasion to inspect this structure in 1930. The first section, built in 1912–1913, was constructed of granite blocks pointed up with 1: 2 mortar. This section has a maximum height of 54 ft. From 1914 to 1918, the dam was raised by constructing a concrete structure back of the initial section and incorporated with it to give a maximum height of 112 ft, The body of the dam is constructed of 1: 5: 6 concrete with about 30% "plums." The up-stream and down-stream faces are of granite. Back of the stone facing on the water side there is a tightening layer of 1: 2½: 3 concrete. The thickness of this rich concrete, measured from the water face, varies from 3 ft at the crown to 10 ft at the top of the original masonry dam. Immediately behind the rich tightening concrete is a drainage system consisting of a double row of vertical drain pipes on 24-in. centers. These vertical pipes are connected to a horizontal header, which empties into the inspection gallery, whence the water is conducted to the down-stream face of the dam.

An effort was made to inject cement into the tightening layer during the summer of 1927, in two adjacent blocks of the structure, which constituted a length along the crown of 180 ft. In all, thirty-seven grout holes and six observation holes were bored for testing and grouting. They were located about 3 ft from the up-stream face and were bored vertically to depths varying from 50.4 ft to 72.8 ft. Near the bottom, the holes were 5.9 ft from the up-stream face and 4.6 ft from the vertical drain pipes. A total of 2 300 ft of ordinary injection holes were bored, together with 390 ft of observation holes.

The first holes were spaced 9.8 ft apart, but the distance was found to be too great and intermediate holes were bored. Pressure tests and observations indicated that the 4.9-ft spacing was still too great, but it was not decreased. The holes were not bored to their full depth at one time, but in stages, depending on the soundness of the concrete. The tightness of each length of hole was tested by water pressure. Cement was injected at a pressure varying at the nozzle from 0 to 294 lb per sq in. A total of 276 600 lb of cement was used, divided into the four groups of holes as shown in Table 4. The part of the dam under treatment had an area of about 11 300 sq ft. Therefore, more than 24 lb of cement was used per sq ft of dam surface.

---

[3] Assoc. Engr., Tennessee Val. Authority, Pickwick Dam, Miss.

For Groups Nos. 1, 2, and 3, Table 4, a mixture of approximately equal parts of cement and water was used, or about 9.9 lb of cement per gal of water. A thin mixture (3.9 lb per gal) was used in Group No. 4. As shown in Table 4, an average of 113.7 lb of cement per ft of hole went into Group No. 1, where the distance between holes was 9.9 ft, whereas only 54.5 lb of cement per ft went into Group No. 2, which was placed midway between the holes of Group No. 1. There was considerable variation, however, between the cement use of the different holes. Injection in five of the six observation holes, which were placed between the holes of Groups Nos. 1 and 2, showed the largest average use of cement—127 lb per ft of hole. A thin mix of 3.6 lb of cement per gal of water, was used for these holes. The injected material had probably spread over a large area, especially up stream to the stone facing and down stream to the drainage system. For the most part, the cement was injected when the lake level was low, but some holes were treated when the water level was at its full height. The leakage water did not seem to indicate a severe loss of cement.

TABLE 4.—CEMENTATION RECORD, RINGEDALSVAND DAM, NORWAY

Group No.	Cement used, in pounds	Total length of bore holes, in feet	Average use of cement, in pounds per foot
1	70 600	621	113.7
2	29 900	548	54.5
3	126 900	1 126	112.7
4	49 200	390	126.0

The objective which was set up at the beginning of the work, respecting the clogging of the drainage system, was not attained. The cement paste did not reach the inspection tunnel except in a few places, but the drainage system was put out of operation at several places, as evidenced by the leakage which appeared on the down-stream face of the dam directly back of the injected section. Measurement of the leakage before and after the cement injection showed that about 76% of the leakage was stopped.

The following conclusions were drawn from the cement injection trial at the Ringedalsvand Dam:

(1) The result of the injection was not fully satisfactory. Even if a large part of the leakage was stopped, a relatively large part still remained. Removal of soluble material in the concrete would continue, therefore and it would probably only be a question of time until the injection must be repeated.

(2) Pores, holes, and passages in the concrete were partly filled with a dark organic slime, or had a coating of slime on the wall surfaces. During the injection the cement would mix with the slime, and the slime would possibly hinder or weaken the setting and hardening of the cement. In all cases there would be a film of slime between the concrete surface in the pores and holes, and the injected cement.

(3) For a dam with a drainage system immediately behind the tightening layer, it will be difficult with cement injected in the foregoing manner to

prevent partly filling the drainage system. Therefore, leakage will find a way through the lean concrete in the down-stream part of the section, and wash out the soluble portion.

Due to the foregoing disadvantages of the cement-injection method, it was not continued and other solutions were studied for the repair of the dam. The adopted method of reconstruction, begun in 1929, consisted of building a concrete flat-slab dam 6½ ft in front of the up-stream face of the old dam and resting against it on struts. The new vertical deck was proportioned to take the full water load so that the only purpose served by the original dam is as a support. This work was completed in 1931.

F. F. Fergusson,[4] Assoc. M. Am. Soc. C. E. (by letter).—Because it is a record of a difficult work, completed satisfactorily, and because its author has given such precise detail as to the method followed, this paper should prove of great practical value. It is particularly interesting and valuable to engineers in India because it draws attention to weaknesses in a type of construction which is probably peculiar to that country, namely, the use of lime instead of cement mortar or Portland cement concrete, in hydraulic structures.

The widespread use of lime is due to its general occurrence geologically in the form of "kankar", the ease with which it is quarried and prepared, and, consequently, its cheapness as compared with cement. The cost of masonry work in lime mortar in the region around Jodhpur is less than one-half that of masonry in cement mortar and less than one-quarter the cost of massive concrete work; these considerations force the engineer to use the lime prepared locally for almost all work, important or otherwise.

The weakness of lime when used for hydraulic works, such as dams, canal walls, and overflow weirs, is abundantly in evidence in many parts of India, but probably no where more so than in Rajputana, where the surface of the country is littered with masonry walls of all sizes built across stream beds and depressions for the purpose of arresting the flow of water and storing it for use during the few months immediately succeeding the monsoons, when wheat cultivation is undertaken. At some time or other during their life, a high percentage of these walls or dams have been breached, and the reason puzzled the writer because many of the structures observed were statically stable even with greater overtopping than could have occurred. Eventually, it was traced to the fact that water gains access through joints in the mortar and eventually passes through the wall, leaching out the lime in its passage. This action has been found to be especially drastic in a wall through which the writer had to cut recently in making some modifications. The wall, which is subjected to a pressure due to 25 ft of water, is 5 ft thick at the ground level and is backed by a bank of sand on both sides, the bank on the water side being pitched to protect it from wave action. The rock used in the masonry is a hard rhyolite that splits with smooth faces. It has been found that the lime has poor adherence to this stone and probably this may be said of the trap-rock, of which the dams described in Mr. Cole's paper, are constructed. It is also a well-known fact in Rajputana that the local masons prefer to work with sandstone and not with granite or rhyolite, because they find difficulty in making the lime "stick" to the stones.

---

[4] Senior Executive Engr., Public Works Dept., Marwar State, Jodhpur, Rajputana, India.

The writer has constructed several small dams in sandstone or rhyolite, according to the geological formation of the locality, but in all cases the greatest care has been exercised to grind the lime fine and to use a mixture of 1 part lime to 1 part clean sand, to avoid regular courses in the masonry, and, finally, to rake out the mortar in both the up-stream and down-stream faces, and to point deeply with a mortar consisting of 1 part cement to 2 parts fine clean sand. This procedure has prevented leaks effectively and should form a rigid part of all specifications for this class of work.

The author's reflections on the stability of gravity dams is also of interest, as the writer has in his jurisdiction a 25-ft masonry dam, built about forty years ago, in which the resultant, due to water level with the crest, falls far outside the middle-third. The masonry is so deplorably poor that the dam is emptied through leaks within a few weeks of filling; it has had a 3-ft surcharge over its entire length and yet has shown no sign of failure. Notwithstanding these facts the writer agrees entirely with the author's final paragraph.

JOSEPH WRIGHT,[5] M. AM. SOC. C. E. (by letter).—This is a most concise and thorough account of a novel and interesting job well done, wherein experience, meticulous care, and a full understanding of the difficulties encountered, and the hazards, involved, were conspicuously essential to the success attained. The profession is much indebted to the author for a full and clear description of the work.

The work on these important Indian dams indicates not only what may be done to save defective dams, but emphasizes more forcibly what must be done to avoid such defects. A dam that permits water to percolate through it cannot be classed as a safe, permanent structure, whether built of stone or concrete, and the remedy is to use a dense concrete or mortar well placed, with special care given to construction joints.

The close spacing and total length of drill holes required and the quantity of cement used is staggering, but is not surprising when it is considered that the dams are of uncoursed rubble masonry and that much of the grout would inevitably be lost in the reservoir or through the down-stream face. For a few of the most serious of these leaky holes the writer is inclined to think the use of asphalt by the "Christians'" process would have saved many tons of cement which found its way out of the dam section, and would have facilitated the cementation process.

Since no dimensions are given upon the dam sections shown, the author's comments concerning their refusal to fail as would be expected in accordance with accepted principles of instability, cannot be verified. The sections do seem light; and although the writer can agree fully that dam builders should take no "chances on the soundness of their materials, or the competence of their workmanship and field direction", he cannot agree that any chances should be taken in the provision for uplift. If all dams were founded upon basalt, or granite, one might reduce the allowance for uplift with safety. Dams fail more often by sliding upon strata beneath their bases; and where the foundation rock is stratified and horizontally bedded, it is believed that designers err more often in the other direction. In his closing discussion, it is hoped that the author will supply dimensions of dam sections, and will show the resultants of forces acting upon their bases.

---

[5] Care, U. S. Engr. Office, Nashville, Tenn.

CHARLES W. COMSTOCK,[6] M. AM. SOC. C. E. (by letter).—The unusual and almost unprecedented character of the work described, together with the author's clear, complete, and interesting account of methods, difficulties, and results, make this paper unique and, therefore, worthy of something more than casual and perfunctory discussion.

In order fully to appreciate the situation which the author's work was intended to, and undoubtedly did, improve, and how such a condition of affairs could come about, it is necessary to cast a glance backward over the development of hydraulic construction in India.

Masonry dams exceeding 100 ft in height, and about a mile long, were undertaken by the Public Works Department prior to 1870 and pushed to completion within a few years. These were the early years of the theory of dam design developed by Sazilly, Delocre, and Rankine, and not much had materialized from it except the rule of the middle third. During the ensuing third of a century many dams between 100 and 200 ft in height, each comprising more than 500 000 cu yd of masonry, were designed on this principle and constructed in various parts of the country. Because the dams were long the sections were made as small as possible, and it was considered good practice to bring the lines of pressure as near as possible to the limits of the middle third. This resulted in sections rather more slender than are to-day thought conservative.

As to materials, they were those which the country afforded. The earlier works would not have been possible otherwise. Portland cement, of course, was known, but it was manufactured in but few localities, was costly, and was little understood. Concrete was practically unheard of. The origin of surkhi mortar is shrouded in the mysteries of the past, but its preparation and use are common knowledge among the Indian masons. It has unquestionable hydraulic properties, and tests have shown compressive strengths of 68 tons per sq ft at 12 months, and 79 tons at 18 months; respectively, 1 060 and 1 230 lb per sq in. Such material cannot be summarily dismissed from consideration.

The Indian people are essentially agriculturists. They are not mechanically minded. Elaborate and complicated machinery does not enter into their scheme of things, although their skill and patience in many handicrafts are revelations to the Westerner. Time is not important to them. They do not think in terms of the individual's span of life.

---

[6] Jackson Heights, N. Y.

In these circumstances it is not surprising that the administrators of the Indian public works designed and built as they did—with a rudimentary theory, native materials, a minimum of mechanical equipment, and a maximum use of manual labor of the kinds to which the people were accustomed. After half a century without a major failure, notwithstanding the construction of a great number of large and important works, they were justified in considering their practice sound, and it is not strange that they were slow to adopt the later developments in materials and methods.

With this background the engineer who designed the Walwhan and Shirawta Dams, and who had spent most of his long professional life in India, naturally preferred to follow a tried and proven road rather than to pursue what might be only a will-o-the-wisp.

The Shirawta Dam contains about 650 000 cu yd of masonry. To construct such a volume, almost entirely of one-man stone, by hand labor within a few working seasons required an army of men and women. These literally swarmed all over the work. In fact, seen from an elevation and from a little distance the activity resembles nothing so much as a gigantic swarm of bees. The labor turnover is enormous, for these people will work on outside employment only during such times as their personal agricultural operations do not require attention.

Herein lies the weakness of the system. Really good masonry can be and has been executed by this somewhat primitive procedure, but with hundreds of masons distributed over a large area and served by thousands of coolies who bring the stone and mortar, adequate supervision and inspection are impossible. Here and there a careless or indifferent mason, an occasional batch of improperly ground mortar, a few stones which are dirty or cracked—the result is a weak spot, a discontinuity, to and through which water under pressure may find its way. Time and the never-ending erosion by running water do the rest.

Thus the slowly but steadily increasing leakage through these dams was regarded as symptomatic of a condition which should not be allowed to persist. The loss of water was unimportant, at least in any quantity which might be reached for some years. It was not believed that the dams were unsafe, but it seemed certain that they would become so if the deterioration should be permitted to continue. If that time should come, every one would be helpless. An edict of condemnation by Government would be a futile gesture, for no power on earth could prevent those reservoirs from filling. The waste-gates, designed only for use in the early stages of construction, are not large enough to empty the reservoirs in the period between monsoons.

To order the dams breached so that the reservoirs could not fill would deprive the City of Bombay and surrounding territory of tramway service, light, fans, and refrigeration. It would shut down about 80 cotton mills and deprive the railroads entering Bombay of power. In short, it would mean ruin and pestilence to a million and a half people. The Indian Government does not take a fiendish delight in destroying private capital, but even if it were indifferent to such destruction it could not face this possibility. On the other hand, failures of the dams would mean frightful havoc to agricultural regions below, and almost certainly much loss of life.

Clearly, the damage already suffered must be repaired and the structures must be rendered permanently immune to future deterioration, without interfering with the use of the reservoirs. The plan adopted after thorough investigation and careful study was endorsed by some of the most experienced engineers in India and received Government approval. The engineers for the contractor, François Cementation Company, Ltd., believed, in the light of their experience, that it promised success. They had not previously undertaken a precisely similar job, but no major engineering problem is an exact duplicate of any other. It was believed that cavities existing in the masonry, whether resulting from carelessness during construction or from subsequent washing out of mortar, could be filled with good cement grout, and that the old surkhi mortar in the neighborhood of these cavities might to some extent be impregnated with cement. It is the execution of this plan which has been so well described by the author.

It has been objected by some persons that the degree of betterment is uncertain since there is no visual evidence that all cavities are filled wholly or in part. No visual evidence, it is true, but the volume of cement retained in the structures (in the case of Shirawta 0.6% of the total volume of the masonry) is very convincing, especially as the pressures employed were sufficient to force the grout through minute openings. It is not claimed, of course, that the dams are of as high quality as though they had been originally laid up in cement mortar under close inspection, but they are certainly as good as (probably even better than) any of those built with surkhi mortar in the manner prevailing in India, and many of which have served for more than fifty years without manifesting any sign of distress.

It has been said that this work was almost unprecedented. The grouting of rock formations underlying dams prior to construction is a well-established practice, as is also subsequent grouting of parts of the structure through holes left for that purpose.

Grouting at the Camarasa Dam in Spain, completed in 1931, was not a parallel case to the Indian dams. At Camarasa the dam was absolutely tight and sound; leakage through the surrounding and underlying rocks was the fault to be remedied. This object was accomplished with marked success.

The Delta Barrage, in Egypt, consists of a series of piers, each 16 m long by 2 m thick and about 14 m high. These are spaced 7 m on centers, and rest on a continuous concrete mat 4 m thick. Construction was begun about the middle of the Nineteenth Century. As a result of political interference the foundation work was not properly done, cracks and settlements appeared almost immediately, it was impossible to maintain the pool level which had been intended—the dam was a failure. When Sir Colin Scott-Moncrieff became head of the Public Works Department in Egypt he took immediate steps to remedy the difficulties. The final stage of the repair job was to drill five vertical holes along the axis of each pier and to inject cement grout. No pressure was used except that due to static head; however, cement injected at one pier frequently appeared in the holes in adjoining piers. One pier took as much as 73 tons of cement; a total of 1 000 tons was used in 132 piers. This work was completed in 1898 or 1899; the dam has given no trouble since.

One work which in some respects parallels the Indian dams is the "barrage de l'Oued Fergoug" in Algeria. This dam, 34 m high, also was designed in the early days of the middle-third theory, construction completed about the beginning of 1872. Like the Indian dams, it was built of one-man rubble by native workmen using lime mortar, perhaps feebly hydraulic. From the beginning it leaked profusely at many places, and lime deposits on the down-stream face indicated serious destruction of the mortar. In December, 1881, a length of 125 m of the highest part of the structure was carried away, most of it clear down to the foundation. Between 1881 and 1885 the gap was filled by a new structure of slightly greater section than the old, but built in the same manner and with the same kinds of materials except that some hydraulic lime and some Portland cement were used in places regarded as especially critical. The dam continued to leak but in 1900 it withstood an unprecedented flood with no indication of weakness. In November, 1927, there was another major failure, carrying away a part of the old and a part of the later work, and resulting in heavy loss of life and property. For some time prior to the failure the authorities had been disturbed over the persistent leakage and the continual leaching of lime from the mortar, and had approved a project for drilling and the injection of cement. This work was in actual process near the left bank at the time of the failure, but had not progressed far enough to throw any light on the condition of the masonry. Whether this method of reinforcement and stabilization would have been effective if undertaken a few years earlier can only be conjectured.

The outstanding peculiarity of hydraulic construction in India is the general aversion to the use of Portland cement. This was understandable in the early days when cement would have had to be imported from Europe and would have been very costly. To-day, however, excellent Portland cement, meeting all standard specifications, is manufactured at several places in India and can be purchased at the factory at prices of about 35 rupees per ton—equivalent to about 9 shillings per bbl—so that this reason is no longer operative.

The late Robert Batson Joyner, who spent nearly a life time in India, and who designed Walwhan and Shirawta Dams and their appurtenant works, wrote[7] in 1919:

> "Indian engineers never use Portland cement in the construction of masonry dams, whether of stone or of concrete, except perhaps in wet foundations; not merely on account of its high cost—though good cement is now being made in the country more cheaply—but also because it is considered inferior to good hydraulic-lime mortar for dams. Cement work is too rigid, whilst the hydraulic-lime mortar, being somewhat elastic, withstands the variations of temperature without cracking. There is therefore not the somewhat alarming necessity of providing expansion joints. The range of temperature is probably not greater in India than in England, but it may occur more suddenly."

---

[7] "The Tata Hydro-Electric Power-Supply Works, Bombay," by the late Robert Batson Joyner, *Minutes of Proceedings*, Inst. C. E., Vol. CCVII, p. 55.

These are arguments devised to justify an existing practice rather than reasons on which that practice is based. The reader may judge for himself of their validity.

With increasing education of Indian masons in the properties of Portland cement, and with the gradual change in personnel of the Public Works Department with the retirement of the seniors and the advent of younger men, it is probable that Indian practice in dam construction will eventually come to conform quite closely with that in other parts of the world. Tradition is strong in the East, and the inertia of 350 000 000 people is not easily overcome.

One of the most valuable features of this paper is that it emphasizes the dominant importance of execution, as compared with design, in the construction of masonry dams. Volumes of mathematical formulas and theoretical discussions in many languages have come and gone, each purporting to be the last word as to stresses in dams; yet sections have changed little in seventy-five years. On the other hand, with few exceptions, all important dam failures have been traced to defective materials or faulty execution. A dam is made safe, or otherwise, on the job—not in the office.

The author is entitled to great credit for his masterly handling of a difficult job. He is further to be commended for the exhaustive and incisive manner in which he has presented the subject in print. There is nothing superfluous; nothing has been omitted. Aspiring authors of engineering papers should be referred to this as a model.
